Abstract

Frogs play an important role in the Earth’s ecosystem, but the decline of their population has been spotted from locations around the world. Monitoring frog activity can assist conservation efforts, and improve our understanding of their interactions with the environment and other organisms. Traditional observation methods require ecologists and volunteers to visit the field, which limit the scale for acoustic data collection. Recent advances in acoustic sensors provide a novel method to survey vocalising animals such as frogs. Once sensors are successfully installed in the field, acoustic data can be automatically collected at large spatial and temporal scales. For each acoustic sensor, several gigabytes of compressed audio data can be generated per day, and large volumes of raw acoustic data have been collected. Enabling automated species identification in acoustic data has become very important to gain insights about frogs and the environment. Most previous studies on machine learning for frog calls often have two limitations: (1) frog recordings often have a higher SNR ($\geq 15dB$); (2) each individual recording contains only a frog species. However, most recordings typically have a low SNR and contain multiple simultaneously vocalising frogs. This thesis aims to address those two limitations, and has the following contributions.

- (1) Develop a fused feature set from temporal, perceptual, and cepstral domains for improving the performance of state-of-the-art frog call classification methods using high SNR recordings (Chapter 3).

Various acoustic features have been developed to classify frog calls, and most features can be categorised into three types: temporal feature, perceptual feature, and cepstral feature. Most previous studies only use features from one domain or two domains, which cannot effectively classify those frog species that share similar acoustic attributes in those one or two domains. In this thesis, a novel fusion of temporal, perceptual, and cepstral features is proposed, so that those frog species share similar acoustic attributes in one or

two domains can be successfully classified. An intensive analysis shows that our fused feature set consistently outperforms the state-of-the-art classification system using high SNR recordings.

- (2) Propose a novel cepstral feature based on adaptive frequency scaled WPD to classify frog calls using both low and high SNR recordings (Chapter 4).

Existing approaches have widely used cepstral features (MFCCs) for frog call classification, and have demonstrated high performance. However, cepstral features are also found to be very sensitive to the background noise. This thesis proposes a novel cepstral feature using adaptive frequency scaled WPD, and the scale is adaptively generated by applying k-means clustering to dominant frequencies of all the frog species to be classified. Compared to Mel-scale, the adaptive scale can better reflect the frequency distribution of those frog species to be classified. Therefore, cepstral features calculated from adaptive frequency scaled WPD can capture more frequency information than Mel-scale. Experimental results demonstrate that the proposed cepstral feature outperforms existing cepstral features that have been used for animal call classification.

- (3) Design a novel MIML framework to classify multiple simultaneously vocalising frog species in low SNR recordings (Chapter 5).

One individual recording contain only one frog species is an assumption that widely existed in the previous studies, but most recordings collected using acoustic sensors contain multiple frog species. This thesis proposes to use MIML learning to classify multiple simultaneously vocalising frog species with AED. A novel frog syllable segmentation method using AED is proposed with limited annotated frog recordings. Compared to other AED methods, our proposed AED can achieve a better syllable segmentation results. With segmented syllables, frog call classification is realised using three MIML classifiers and low-level features extracted from segmented syllables. Experimental results show that the proposed MIML classification framework can achieve a better performance compared to the SISL classification.

- (4) Design a novel ML framework to classify multiple simultaneously vocalising frog species in low SNR recordings (Chapter 6).

The weakness of the MIML classification framework is that the classification performance is highly affected by AED results. One solution is to prepare large volumes of

annotated acoustic data and apply supervised learning algorithms for improving segmentation results. Another is to used a different framework without the need of syllable segmentation. This thesis examines the latter option and proposes a ML classification framework to classify multiple simultaneously vocalising frog species. A novel feature set using LPCs and multi-stage AWSCCs is proposed for the ML classification. Experimental results show that ML classification results outperform MIML classification results.

Acknowledgments

First, I would like to express my sincere gratitude and thanks to Dr. Jinglan Zhang (principal supervisor), for giving me an opportunity to study in Australia. During the entirety of this PhD study, I have learnt so much from her about having passion for work, combined with high motivation, which will benefit me throughout my life. I would also like to express my gratitude to Prof. Paul Roe (associate supervisor), for his consistent instructions and supports through the last three years.

I would also like to thank Dr. Michael Towsey (associate supervisor) for his provision of consistent guidance, discussions, and encouragement during my PhD study. Michael's attitude towards scientific research keeps motivating me go deeper into research.

I want to thank Prof. Vinod Chandran (associate supervisor) for his support in writing my confirmation report and this thesis. Vinod's strong background knowledge in signal processing greatly helps me improve my understanding of this research.

I would also like to express my gratitude to my family, especially my grandparents, parents and my wife. They have always supported my overseas study. Without their support, I could not give my full attention to PhD study and the completion of this thesis. My sincere thanks also go to all my friends for their love, attention and support to my PhD study.

Finally, I extend my thanks to the China Scholarship Council (CSC), Queensland University of Technology and the Wet Tropics Management Authority for their financial support.

Chapter 1

Introduction

1.1 Motivation and Overview

Over the last two decades, rapid decline in frog populations, which is regarded as one of the most critical threats to the global biodiversity, has been spotted from locations around the world. The causes for this decline are many, but an emerging disease called *chytridiomycosis* [Mutschmann, 2015] and global climate change [Carey and Alexander, 2003] are thought as the biggest threats. On the one hand frog populations are declining rapidly, but on the other, frogs are greatly important to the Earth's ecosystem. Frogs are an integral part of the food web, and are often considered as a valuable indicator for their sensitivity to the environmental change [Böll et al., 2013]. Those aforementioned reasons necessitate the development of better tools to monitor frogs. Frogs are often much easier to be heard than seen (Figure 1.1).

Figure 1.1: Photos of frogs to indicate that frogs are difficult to be seen in the field

Also frog vocalisations are often employed for most communications, which offer a possible way to study and evaluate frog populations by detecting species-specific calls [Dorcas et al., 2009]. Traditional methods require ecologists and volunteers to physically visit sites for acoustic data analysis, which are costly and time-consuming. Although traditional methods can provide an accurate measure of daytime species and richness, the scale limitation in both spatial and temporal domains is unavoidable.

To address this limitation, recent advances in acoustic sensors provide a way to automatically survey vocal animals (such as frogs). Deploying acoustic sensors in the field, frog vocalisations can then be automatically collected. Compared to the manual point-counting method, sensors can greatly extend the survey into larger spatial and temporal scales, and generate large volumes of acoustic data that needs to be analysed. Consequently, enabling automatic species identification in acoustic data has become important. However, audio data, which are collected using acoustic sensors in the field, tends to be noisy. Very often the desired signal (frog call) is weak, and there are other overlapping signals such as bird calls/insect calls over frog calls. Furthermore, different frog species tend to call together to make a chorus. All those characteristics pose a big challenge to performing automatic classification of frog species in audio data collected by sensors.

1.2 Basic concepts

In this section, some basic concepts are given to better describe the research problem and questions, aims and objectives, significance and contributions.

1.2.1 Commercial recordings VS Environmental recordings

Audio data used in this thesis is derived from two sources: David Stewart's commercial recordings [Stewart, 1999] (high SNR and one species per recording) and James Cook University's environmental recordings (JCU)¹ (low SNR and multiple species per recording). Here, frog recordings from David Stewart's CD have a high SNR and each individual recording has only one frog species. For those JCU recordings, they have a low SNR, and most of them contain multiple frog species. Since almost all prior work for frog call classification has an assumption

¹All the recordings can be requested and obtained from our group website: <https://www.ecosounds.org/>

that each individual recording contains only one frog species. To make a direct comparison with those previous studies, two experiments are designed using high SNR recordings. However, most field recordings contain multiple simultaneously vocalising frog species, we therefore proposed two classification frameworks to study field recordings (JCU recordings): MIML classification and ML classification.

Compared to audio data collected using a directional microphone to record a single frog's calls (David Stewarts CD), environmental recordings are normally collected under unconstrained noisy conditions (such as JCU recordings). Consequently, the noise and variability issues need to be considered when coping with environmental audio data. In terms of the background noise, there are a wide variety of non-biological noises and a variety of animal sounds in environmental recordings. These non-biological noises often come from different sources: rain, wind, human activities (e.g. traffic noise). Besides non-biological noises, many competitive animal sounds (e.g. birds when we are interested in frogs) are also recorded in the environmental recordings. The signal-to-noise ratio (SNR) of CD recordings and JCU recordings are listed in Table A.1 and Table B.1.

Since the power of signal and background noise in this study varies from recording to recording and call to call within the recording, Table D.1 and Table D.2 (Appendix D) show the confidence intervals of high and low SNR recordings for the power of signal and noise.

In the case of variability, it is produced in many aspects: call structure between species, population of one specific species, time and season changes. All those noises and variabilities make it challenging to develop a robust frog call classification system.

1.2.2 Audio data analysis

Audio data is usually considered as a mono-dimensional signal. To ease the tasks of understanding, comparison, modification, and re-synthesis of signals [Rocchesso, 2003], audio data analysis is often developed to find the major features representing the time-varying audio data. Many application areas of audio data analysis have been identified: speech processing, mechanical signal processing, bioacoustics analysis, etc. The two most important audio data analysis techniques are Short-time Fourier Transform (STFT) and Linear Predictive Coding (LPC). STFT is a Fourier-related transform, which determines the sinusoidal frequency and phase content of local sections of a signal as it changes over time [Allen, 1997]. LPC is mostly

used to represent the spectral envelope of audio data based on the information of a linear predictive model [Deng and O'Shaughnessy, 2003]. After STFT, the audio data is transformed into its two dimensional representation (spectrogram), which is widely used for most bioacoustic analysis for its flexible implementation and good applicability. An example of a spectrogram of frog calls derived from a field recording is shown in Figure 1.2.

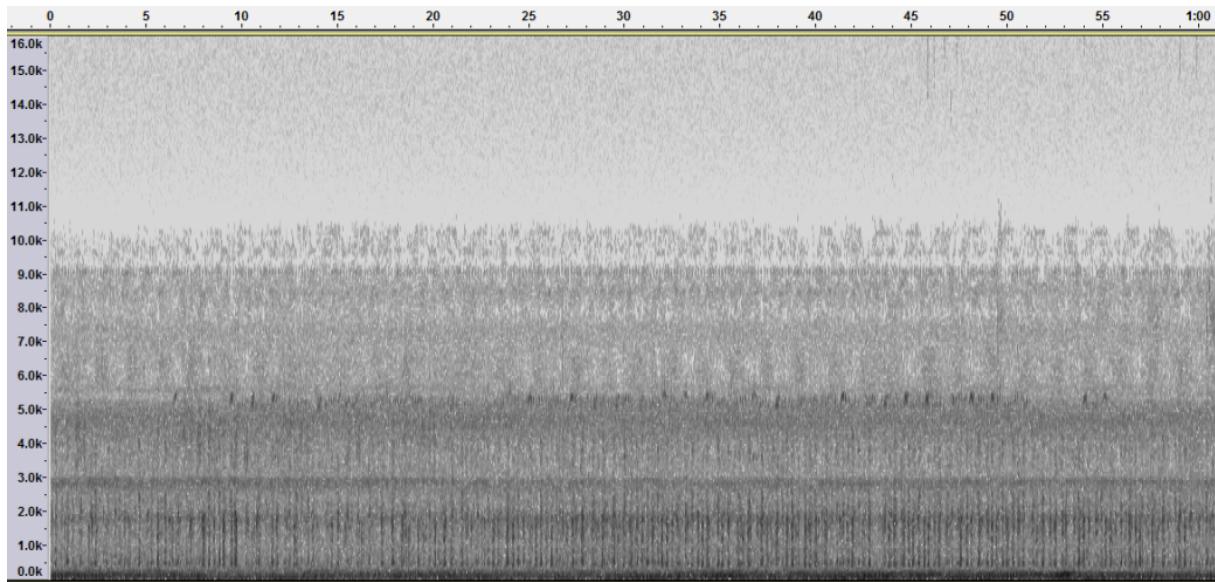

Figure 1.2: An example of spectrogram of environmental recording. The x-axis is time (seconds); the y-axis is frequency (kHz). The spectrogram is generated from a one-minute recording collected in Townsville, Queensland, on around 11.50 pm February 03 2013; the frog species in this recording is *Litoria caerulea*

1.2.3 Frog call structure

In contrast to the hierarchical structure of bird calls, frog calls have a relatively simple call structure [Somervuo et al., 2006]. The frog vocalisation structure mainly has two ingredients: call and syllable. A frog call is normally made up of several syllables (Figure 1.3).

One syllable is basically a sound that a frog produces with a single blow of air from the lungs [Huang et al., 2009]. For frog call classification, an elementary unit is one syllable. To get an intuitive sense of the frog call structure, examples of different frog species in both waveform and spectrogram are shown in Table A.1 and Table B.1. For the waveform, x-axis and y-axis represent time and amplitude scales, respectively. The x-axis and y-axis of the spectrogram represent the time and frequency scales, respectively. The grey scale represents the acoustic intensity.

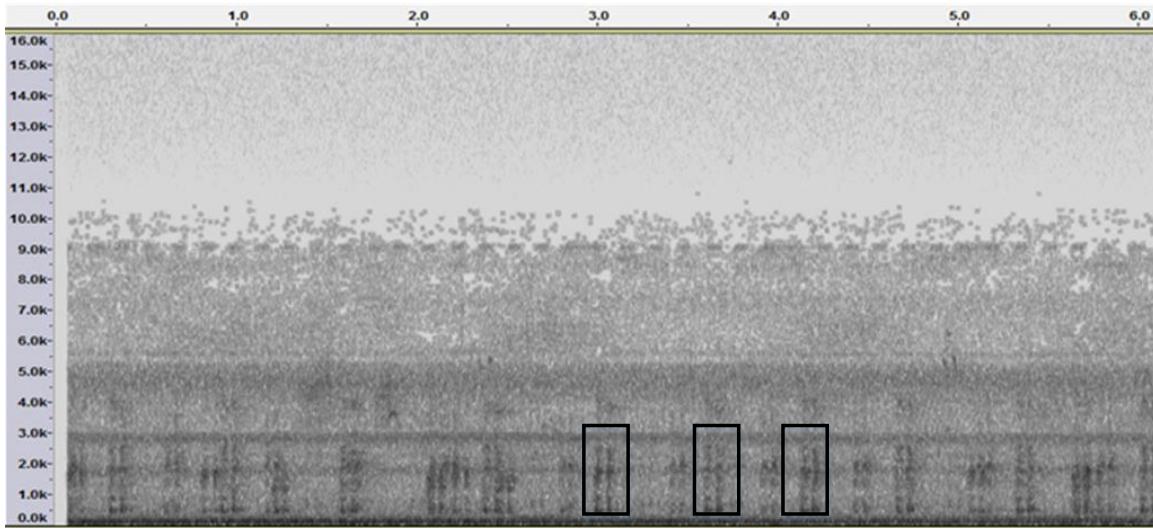

Figure 1.3: Spectrogram of *Litoria caerulea*, three syllable of *Litoria caerulea* are annotated with one black rectangle, respectively.

To the best of this researcher's knowledge, no serious research has explored the frequency range of different frog species. So far, some researchers pointed out that ultrasound can be produced by few frog species [Arch et al., 2008, Narins et al., 2007]. In this research, we focus on those frog species, frequency of which are lower than 8000 Hz.

1.2.4 Acoustic event and background noise

An acoustic event is a localised region of high intensity in a spectrogram. As can be seen from Figure 1.5, there are lots of acoustic events in an one-minute recording. This study focuses on the frog vocalisations, and frog calls are regarded as signals. Consequently, all the other events are called background noise. In this study, both high and low SNR recordings are investigated to build a robust frog call classification system. Most previous studies present the frog call classification system using high SNR recordings. The high SNR recordings often assume that there is only one frog species in each individual recording with few background noises ($SNR \geq 15dB$). In contrast, most low SNR recordings consist of more than one frog species in an individual recording with lots of background noises ($SNR < 15dB$). For the low SNR recordings, Table C.1 shows the power spectral density of signal and noise. It can be seen that the noise in low SNR recordings is often generated by several sources and broadband, which covers different frequency bands and leads to the frequency overlapping between the signal and noise.

1.2.5 Frog call classification

A frog call classification system often consists of four parts (Figure 1.4): (1) signal pre-processing, which includes signal processing and noise reduction; (2) syllable segmentation, which is used to generate a basic classification unit for frog calls; (3) feature extraction; and (4) classification.

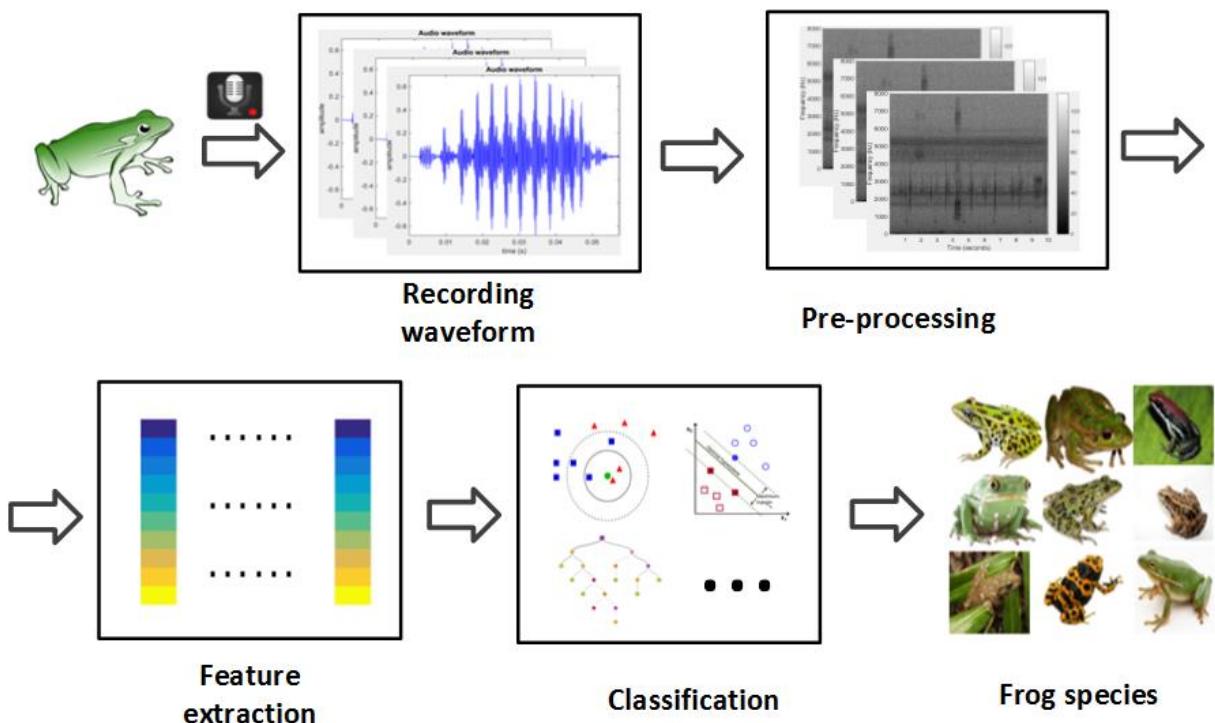

Figure 1.4: Flowchart of a frog call classification system

1.3 Research Challenges

Most datasets used in previous frog call classification studies assume that there is only one frog species in each individual recording. However, these resulting frog calls cannot reflect the characteristics of frog vocalisations in real-world situations, such as background noise, frog chorus, and other vocalising animals. To develop a robust frog call classification system for environmental recordings, two main challenges have been identified.

Challenge 1: Most previous work studied frog call classification using high SNR recordings, but the classification performance of different studies varied a lot with a relatively low classification accuracy. The first challenge of this thesis is to build an enhanced feature set to further improve the classification performance using high SNR recordings.

Challenge 2: Since our work finally aims to classify frog calls in low SNR recordings, most features that can successfully classify high SNR recordings will probably not perform well for low SNR recordings. Consequently, it is still a big challenge to develop robust acoustic features to classify frog species in low SNR recordings.

Challenge 3: Since most previous work assumed that each individual recording consists of only one frog species, a single-instance single-label (SISL) framework is suitable for classifying frog calls in those high SNR recordings Figure 1.5. However, as low SNR recordings often have different characteristics containing more than one frog species, the SISL framework is no longer suitable. Therefore, the last challenge of this thesis is to design a novel classification framework for studying frog vocalisations in low SNR recordings with overlapping vocalising frog species.

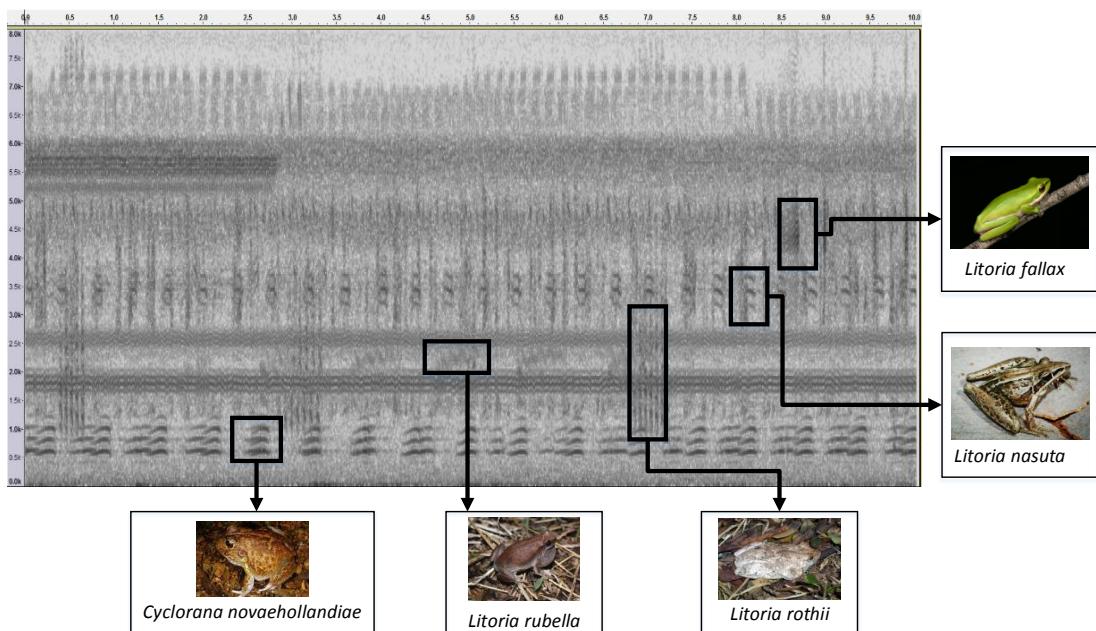

Figure 1.5: An example of collected recording with multiple simultaneously vocalising frog species. Five frog species exist in this 10-second recording: *Cyclorana novaehollandiae*, *Litoria rubella*, *Litoria nasuta*, *Litoria rothii*, and *Litoria fallax*.

1.4 Research questions

The research questions are developed in order to solve the aforementioned challenges, which can be categorised into three parts.

1. How to improve the classification performance when addressing high SNR recordings?
2. How to develop robust acoustic features to classify frog calls in low SNR recordings?
3. How to employ suitable classification frameworks to classify multiple simultaneous vocalising frog species in low SNR recordings?

1.5 Aims and objectives

This thesis aims to investigate techniques for robust and effective classification of frog species in acoustic data for environmental monitoring. For high SNR recordings, we need to improve the classification performance. As for the low SNR recordings, we plan to design novel frameworks to classify multiple simultaneously vocalising frog species. With our classification results, ecologists can then make decisions on how to protect and improve the health of frog populations. The specific research objectives are listed below.

1. To improve the current representation schemes for modelling frog calls in high SNR recordings
2. To develop robust feature extraction methods for frog call classification in low SNR recordings
3. To investigate machine learning techniques (multiple-instance multiple-label (MIML) learning and multiple-label (ML) learning) to tackle the frog call classification problem in low SNR recordings

1.6 Significance and contributions

Due to the development of sensor techniques, acoustic sensors have been widely deployed in the field for surveying vocalising animals. Different from recordings collected in the constrained environment, recordings collected in the field often have a low SNR and contain multiple simultaneous vocalising frog species. In this dissertation, the performance of classifying frog species in high SNR recordings is investigated to be further improved. Then, features that can be used for studying frog calls in high SNR recordings are developed or adapted for analysing low

SNR recordings. Since field recordings often consist of multiple simultaneous vocalising frog species, both MIML and ML learning are used for the classification of frog species in low SNR field recordings. Meanwhile, both frog calling activity and species can be monitored over long-term using our proposed classification framework. Further more, ecologists can monitor frogs by collecting audio data with the developed frog call classification framework, which will enable frog monitoring over large areas and long periods of time, and significantly reduce the expert labour cost for monitoring frog calling activity of a particular area. The monitoring results can also help reveal the importance of environmental protection, which can be achieved via studying the correlation between the frog calling activity/species richness and weather variables.

Below is a list of the publications arising from this PhD research.

1.7 Thesis structure

This thesis is organised in the manner outlined in Figure 1.6

Detailed description of each chapter is shown below:

- Chapter 1 provides a brief introduction to the problem of "Acoustic classification of Australian frogs for ecosystem surveys". The background and motivation are first discussed. Then five basic concepts related to frog call classification are presented to lay the foundation for this research: environmental audio data, audio data analysis, frog call structure, acoustic event and background noise, and frog call classification system. Next, research problems and questions, aims and objectives, significance and contributions are presented based on those five basic concepts. To be specific, there are three main objectives in this thesis. The remaining chapters are organised in the order of addressing those three objectives.
- Chapter 2 reviews the significant and latest literature in the field. The discussion divides

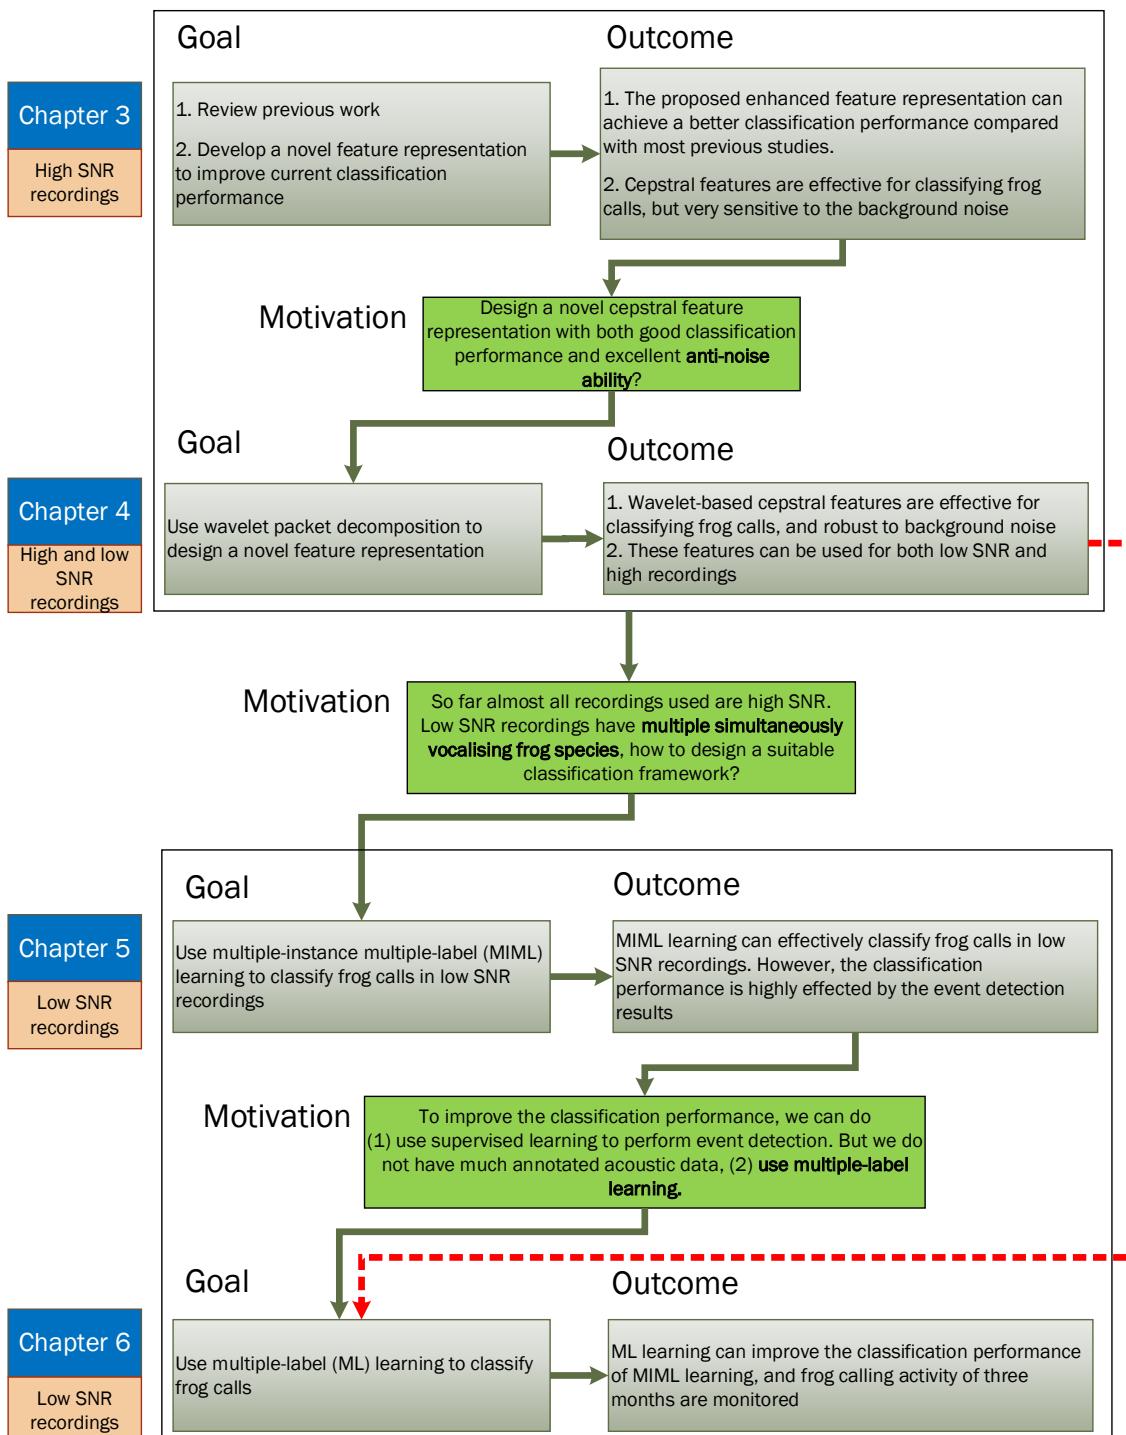

Figure 1.6: Structure of the four main chapters of this thesis

the frog call classification system into three parts: signal pre-processing, feature extraction and classification. In addition, there are reviews for evaluation methods and previous experimental results. This chapter intends to provide the reader with a foundation for the research problem and necessary information about the state-of-the-art developments in

the field. Furthermore, the research gap in current literature is identified, leading to the direction for the following research.

- Chapter 3 presents an enhanced feature set for frog call classification in high SNR recordings. An enhanced feature set is constructed via the combination of temporal, perceptual, and cepstral features. Five machine learning algorithms are evaluated with our proposed feature sets. This chapter aims to (1) review previous features used for frog call classification and develop a better feature set; (2) explore those previous features and study which can be adapted from high SNR recordings to low SNR recordings.
- Chapter 4 discusses wavelet analysis for frog call classification. According to the conclusion from Chapter 3, it is found that a cepstral feature can achieve higher classification accuracy compared with temporal and perceptual features but it is very sensitive to the background noise. Consequently, in this research, a novel cepstral feature has been designed with wavelet packet decomposition that has both high classification performance and a good anti-noise ability. It is because this research will move to low SNR recordings from high SNR recordings, rather than only focusing on the low SNR recordings.
- Chapter 5 discusses the use of multiple-instance multiple-label (MIML) framework for frog call classification. To cope with low SNR recordings with multiple simultaneously vocalising frog species, the traditional single-instance single-label classification framework is no longer suitable. Therefore, this research tries to adopt other classification frameworks such as MIML learning and ML learning. MIML learning is presented in this chapter. A MIML classification framework is adopted for studying frogs. A previous study of studying birds used a supervised learning algorithm to segment frog syllables, but needs lots of annotated data. However, there are few annotated frog recordings in this study. An unsupervised learning method is therefore developed to segment syllables, which is named *acoustic event detection* (AED). Then, three MIML classifiers are evaluated with constructed features using a bagging generator. The proposed MIML classification framework can classify multiple frog species in low SNR recordings, but the classification performance is highly affected by the results of AED. Although our AED methods achieves better results compared with previous AED methods, the results still need to be further improved.
- Chapter 6 discusses the use of multiple-label learning for frog call classification. Chapter

5 demonstrates that classification performance is highly affected by AED results. In this chapter, we use ML learning to study low SNR recordings with multiple simultaneously vocalising frog species without the segmentation process. Two experiments are conducted in this chapter. The first is to estimate the frog calling activity using the AED. The second is to estimate the frog species richness using the global feature sets, where the feature sets are modified from those features used in Chapter 3. Furthermore, both frog calling activity and species richness over three months are estimated using the field recordings. The correlation between frog calling activity/species richness and weather variables (mean temperature and rainfall) are studied.

- Chapter 7 summarises and concludes the thesis, and identifies the achievements.

Chapter 2

Literature review

This chapter reviews the extant literature on frog call classification. It aims to give a quantitative and detailed analysis of related techniques used in frog call classification. To the best of our knowledge, previous studies have not used multiple-instance multiple-label (MIML) learning or multiple-label (ML) learning for frog call classification, therefore we focus on the studies of single-instance single-label (SISL) classification of frog calls. For MIML and ML learning, some papers that have studied birds are reviewed.

2.1 Overview

Over the past decade, frog biodiversity has rapidly declined because of frogs' sensitivity to habitat loss and degradation, introduced invasive species, and environmental pollution [Dudgen et al., 2006]. On the one hand, frog biodiversity is rapidly declining, and on the other hand frogs are greatly valuable to the environment. Firstly, frogs are an integral part of the food web, and the decline of their population can result in negative impacts through the whole ecosystem. Secondly, frogs are famous indicator species for environment health. Finally, frogs are very useful in medical research that benefits humans¹. The rapid biodiversity decline and great importance of frogs make it necessary for frog biodiversity monitoring to increase.

To monitor the change of frog biodiversity and optimise frog protection policies, many researchers have shown interest in studying frogs. Compared to counting frogs by visual observation, hearing the vocalisations of frogs is much easier. Consequently, frog vocalisations

¹<http://www.savethefrogs.com/why-frogs>

are often used for monitoring frogs. There are two approaches for acoustic frog monitoring. The traditional field survey methods require ecologists to physically visit sites to collect acoustic data, which is both time-consuming and costly. In contrast, recent advances in acoustic sensor techniques have greatly extended the spatio-temporal scale for acoustic monitoring of frog biodiversity [Wimmer et al., 2013]. The large volumes of acoustic data collected this way make it essential to develop new automated methods of analysis.

Over the last few years, many researchers have described automated methods for detecting and classifying frog calls [Camacho et al., 2011, Chen et al., 2012, Gingras and Fitch, 2013, Han et al., 2011, Huang et al., 2014, 2009, 2008]. However, there is no paper that summarises those methods. In this work, we present a comprehensive survey of frog call classification to provide other researchers with basic information, current methods and trends in this field.

Three parts play important roles in the performance and precision of frog call classification: signal pre-processing, feature extraction, and classification. In this survey, these three important parts of frog call classification are presented as shown in Figure 1.4.

Signal pre-processing consists of signal processing, noise reduction and syllable segmentation. Signal processing here denotes changing a signal from one-dimension (audio data) into two-dimensional representation (image). Noise reduction is essential to improve the classification performance. Since the elementary acoustic unit for frog call classification is the syllable, which is a continuous vocalisation emitted by an individual, segmenting continuous recordings of frog calls into individual syllables is necessary.

Previous studies have developed various methods for feature extraction [Camacho et al., 2011, Chen et al., 2012, Gingras and Fitch, 2013, Han et al., 2011, Huang et al., 2014, 2009, 2008]. Here we review and analyse all the used features: time domain and frequency domain features, time-frequency features, cepstral features, and other features. After feature extraction, numerous classifiers have been proposed for frog call classification. A summary of those classifiers is given in section 2.4.

It is worth noting that most previous researchers used different databases for their experiments because frog call research is often related to geographical regions [Jang et al., 2011]. Consequently, there is still a lack of uniformity in the way classification methods are evaluated and assessed. This survey is not meant to compare all previous frog call classification methods and find the best one, but to assemble all the methods in order to provide a direction for the

classification of frog calls. To be specific, this research mainly surveyed different features used for frog call classification because most studies focus on new features rather than new signal processing techniques, syllable segmentation methods, or classifiers.

The remainder of this survey is organised as follows: In section 2.2, signal pre-processing is presented in its three parts: signal processing, noise reduction, and syllable segmentation. In section 2.3, different acoustic features are investigated for frog call classification. In section 2.4, numerous classifiers are studied for frog call classification. In section ??, experimental results of state-of-the-art research are discussed. Finally, section 2.7 discusses research gaps and 2.8 sums up this chapter.

2.2 Signal pre-processing

Frog call recordings are often collected using a battery-powered acoustic sensor (stored in a weather proof metal box) with an external microphone. After signal acquisition, signal pre-processing is the first step for a frog call classification system. It often consists of signal processing, noise reduction, and syllable segmentation. The research gap in each part of signal pre-processing is described below.

2.2.1 Signal processing

Signal processing often denotes the transformation of frog calls from one-dimension (recording waveform) to two dimensions (time-frequency representation). Two main techniques used for frog signal processing are short-time Fourier transform (STFT) [Colonna et al., 2015, Huang et al., 2014, 2009, Noda et al., 2016], wavelet packet decomposition [Yen and Fu, 2002], and discrete wavelet transform [Colonna et al., 2012b]. STFT is the most widely used technique among them for its flexible implementation and better applicability. Given one frog call $x(n)$, its fast Fourier transform can be expressed as

$$X(k) = \sum_{n=0}^{L-1} x(n)w(n)e^{-j2\pi kn/L}, 0 \leq k \leq L - 1 \quad (2.1)$$

where $X(k)$ is the frequency domain signal (spectrum) and denotes each frame of the spectrogram, and $w(n)$ is the window function. The waveform, spectrum and spectrogram of one

individual syllable for *Mixophyes fasciolatus* is illustrated in Fig. 2.1. Here three representations are consistent with features in three domains: the time domain, frequency domain and time-frequency domain.

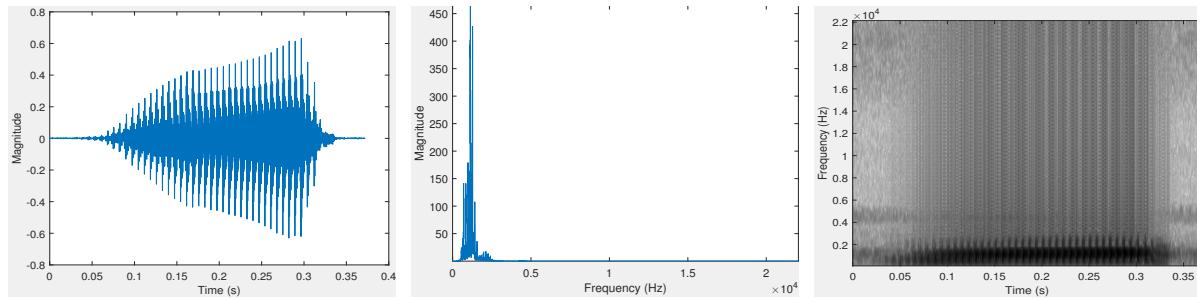

Figure 2.1: Waveform, spectrum and spectrogram of one frog syllable for *Mixophyes fasciolatus*. The window function, size and overlap are Hamming window, 128 samples and 85%, respectively

2.2.2 Noise reduction

Noise reduction is an optional process for frog call classification. Huang et al. [2014] applied a de-noise filter for noise reduction. The wavelet threshold function in the one-dimensional signal was used as the filter kernel function. Bedoya et al. [2014] introduced a spectral noise gating method for noise reduction. Specifically, the selected frequency band spectrum of the frogs' call to be detected was estimated and suppressed. While the aforementioned noise reduction methods can remove some background noise, some of the desired signals will be suppressed. Noise reduction methods are therefore selectively used based on signal-to-noise ratio of the acoustic data and the research problem.

2.2.3 Syllable segmentation

For frog calls, the basic elementary acoustic unit is a syllable, which is a continuous frog vocalisation emitted by an individual frog [Huang et al., 2009]. The precision of syllable segmentation will directly affect the classification performance, since features used for frog call classification are calculated based on each syllable. Frog syllable segmentation methods in previous studies are summarised and listed in Table 2.1. All previous methods cannot address recordings with simultaneous vocalising frog calls. Meanwhile, those methods that used the time domain feature for segmentation, cannot address recordings with low signal-to-noise ratio.

Table 2.1: Summary of related work for frog syllable segmentation. Here, E denotes energy, ZCR denotes zero-crossing rate. Sequential means that syllables are segmented using the same sequence in the recordings.

Authors	Features for segmentation	Procedure
Han et al. [2011]	Spectral entropy	Manual
Jaafar and Ramli [2013a]	E and ZCR	Sequential
Huang et al. [2009]	Amplitude	Non-sequential
Chen et al. [2012]	Spectrogram	Non-sequential
Colonna et al. [2015]	Incremental E and Incremental ZCR	Sequential and real time

2.3 Acoustic features for frog call classification

Developing effective acoustic features that show greater variation between rather than within species is important for achieving robust classification results [Fox, 2008]. For frog call classification, acoustic features can be classified into five categories: time domain features, frequency domain features, time-frequency domain features, cepstral features, and other features.

2.3.1 Time domain and frequency domain features for frog call classification

Time domain features for frog call classification have been explored for a long time [Camacho et al., 2011, Chen et al., 2012, Dayou et al., 2011, Huang et al., 2014, 2009, 2008]. Time domain features are often combined with frequency domain features for frog call classification.

Huang et al. [2009] used spectral centroid, signal bandwidth, and threshold-crossing rate for frog call classification with a k-nearest neighbour classifier (K-NN) and support vector machines (SVM). In another work, Huang et al. [2014] combined spectral centroid, signal bandwidth, spectral roll-off, threshold-crossing rate, spectral flatness, and average energy to classify frog calls using neural networks. Another paper published by [Huang et al., 2008] used spectral centroid, signal bandwidth, spectral roll-off, and threshold-crossing rate for frog call classification. Dayou et al. [2011] combined Shannon entropy, Rényi entropy and Tsallis entropy for frog call classification. Based on this work, Han et al. [2011] improved the classification accuracy by replacing Tsallis entropy with spectral centroid. To classify anurans into four genera, a three-parameter model was proposed based on advertisement calls,¹ which used

¹an advertisement call is produced by a male frog in order to attract females during the breeding season and to warn other rival males of his presence.

mean values for dominant frequency, coefficients of variation of root-mean square energy, and spectral flux [Gingras and Fitch, 2013]. With this model, three classifiers were employed for classification: K-NN, a multivariate Gaussian distribution model and a Gaussian Mixture Model (GMM) [Gingras and Fitch, 2013]. Chen et al. [2012] proposed a method based on syllable duration and a multi-stage average spectrum for frog call recognition. Their recognition stage was completed by the Euclidean distance-based similarity measure. Camacho et al. [2011] used the loudness, timbre and pitch to detect frogs with a multivariate ANOVA test.

2.3.2 Time-frequency features for frog call classification

For frog call classification, we often transform the one-dimensional signal into its two-dimensional time-frequency representation. Then, features based on the time-frequency representation can be calculated for classification. Acevedo et al. [2009] developed two feature sets for automated animal classification. The first was minimum and maximum frequencies, call duration, and maximum power; the second was minimum and maximum frequencies, call duration, and frequency of maximum power in eight segments of duration. With two feature sets, three classifiers were used for the classification: linear discriminant analysis(LDA), decision tree and SVM. Brandes [2008] proposed a method for classifying animal calls using duration, maximum frequency, and frequency bandwidth, and with Hidden Markov Model (HMM) used as the classifier. Yen and Fu [2002] combined wavelet packet feature extraction and two different dimensionality reduction algorithms to produce the final feature vectors. Then, they adopted a neural network classifier for classification. Grigg et al. [1996] developed a system to monitor the effect of the introduced Cane Toad on the frog population of Queensland. The classification was based on the local peaks in the spectrogram using Quinlan's machine learning system, C4.5. Brandes et al. [2006] proposed a method to classify frogs using central frequency, duration, and bandwidth with a Bayesian classifier. Croker and Kottege [2012] introduced a feature vector for detecting frogs with a similarity measure based on Euclidean distance. The feature vector consisted of dominant frequency, frequency difference between the lowest and dominant frequencies, frequency difference between the highest and dominant frequencies, time from the start of the sound to the peak volume, and time from the peak volume to the end of the sound.

2.3.3 Cepstral features for frog call classification

Cepstral features are also popular for frog call classification. These features include Linear Prediction Coding Coefficients (LPCs) and Mel-frequency cepstral coefficients (MFCCs). Colombia and del Cauca [2009] introduced LPCs for frog call classification with a modified K-Means classifier. Jaafar et al. [2013a] introduced MFCCs and LPCs as features, and K-NN and SVM as classifiers for frog call identification. Yuan and Ramli [2012] also used MFCCs and LPCs as features, and kNN as the classifier for frog sound identification. Lee et al. [2006] used the averaged MFCCs and LDA for the automatic recognition of animal sounds. Bedoya et al. [2014] combined MFCCs and a learning algorithm for multivariate data analysis (LAMDA) for frog call recognition. Vaca-Castano and Rodriguez [2010] proposed a method to identify animal species, which consisted of MFCCs, principal component analysis (PCA) and kNN. Jaafar and Ramli [2013a], Jaafar et al. [2013b], Tan et al. [2014] published three papers about frog call classification with MFCCs, Δ MFCC and $\Delta\Delta$ MFCC calculated as features, and kNN and SVM used as classifiers. Colonna et al. [2012a] introduced MFCCs for classifying anurans with a kNN classifier. Noda et al. [2016] fused time domain features with cepstral features for frog call classification which achieved a better classification performance than using only cepstral features. Three classifiers were investigated for the classification: HMM, random forest, and SVM.

2.3.4 Other features for frog call classification

Besides time domain features, frequency domain features, time-frequency domain features and cepstral features, other features are also introduced to classify frog calls. Wei et al. [2012] proposed a distributed sparse approximation method based on ℓ_1 minimization for frog call classification. Dang et al. [2008] extracted the vocalisation waveform envelope as features, then classified calls by matching the extracted envelope with the original signal envelope. Kular et al. [2015] treated the sound signal of a frog call as a texture image. Then, texture visual words and MFCCs were calculated as the features for frog call classification.

2.4 Classifiers

For frog call classification, numerous pattern recognition methods have been used to construct the classifier, such as the Bayesian classifier [Brandes et al., 2006], k-nearest neighbour classifier (kNN) [Colonna et al., 2012a, Dayou et al., 2011, Gingras and Fitch, 2013, Han et al., 2011, Huang et al., 2009, 2008, Jaafar and Ramli, 2013a, Jaafar et al., 2013a,b, Vaca-Castano and Rodriguez, 2010, Yuan and Ramli, 2012], support vector machine (SVM) [Acevedo et al., 2009, Gingras and Fitch, 2013, Huang et al., 2009, 2008, Jaafar et al., 2013a, Tan et al., 2014], hidden Markov model (HMM) [Brandes, 2008], Gaussian mixture model (GMM) [Gingras and Fitch, 2013, Huang et al., 2008], neural networks (NN) [Huang et al., 2014, Yen and Fu, 2002], decision tree (DT) [Acevedo et al., 2009, Grigg et al., 1996], one-way multivariate ANOVA [Camacho et al., 2011], and linear discriminant analysis (LDA) [Acevedo et al., 2009, Lee et al., 2006]. Besides classifiers, other methods for classifying frog species include those based on the similarity measure [Chen et al., 2012, Croker and Kottege, 2012, Dang et al., 2008] and those based on the clustering technique [Bedoya et al., 2014, Colombia and del Cauca, 2009, Wei et al., 2012]. The summary of those classifiers used in frog call classification is listed in Table 2.2. kNN is the most commonly used classifier for its simplicity and easy application. However, the kNN classifier is sensitive to the local structure of the data, as well as to the initial cluster centroids. Therefore, the kNN classifier is often run multiple times based on different initial points. SVM is another classifier that is widely used for its good generalisation ability. However, the performance of SVM can be quite sensitive to the selection of the regularisation and kernel parameters, and it is possible to over-fit when tuning these hyper-parameters. Therefore, selecting suitable parameters for SVM is very important and is realised by grid search in most previous studies [Hsu et al., 2003].

2.5 MIML or ML learning for bioacoustic classification

To the best of this author's knowledge, there is still no paper that uses MIML or ML learning to focus on frog call classification. In contrast, some previous research has applied MIML or ML learning to study bird calls.

For MIML learning, [Briggs et al., 2012] introduced the MIML classifiers for acoustic classification of multiple simultaneous bird species. In their method, a supervised learning

classifier (random forest) was first employed for segmenting acoustic events. Then features were extracted from each segmented acoustic event. Before putting features into classifiers, a bag generator was used to construct a bag-level feature. Lastly, three MIML classifiers were experimentally evaluated: MIML-SVM (support vector machines Based Multi-Instance Multi-Label Learning Algorithm), MIML-RBF (MIML Radial Basis Function), and MIML-kNN (k-Nearest Neighbor Based Multi-Instance Multi-Label Learning Algorithm). [Dufour et al., 2013] used Mel-filter cepstral coefficients and three MIML classifiers to classify birds. To be specific, Mel-filter cepstral coefficients were first calculated for each frame. Then two new feature vectors were computed to represent longer segments. Lastly, three MIML classifiers were experimentally evaluated: MIML-RBF, MIML-kNN, and M3MIML (Maximum Margin Method for Multi-instance Multi-label Learning).

For ML learning, several papers have been published in the Neural Information Processing Scaled for Bioacoustics (NIPS4B challenge), which classified birds, insects, and amphibians recordings, followed by pre-processing and segmentation, feature extraction, feature selection, and classification [Chen et al., 2013, Lasseck, 2013, Massaron, 2013, Mencia et al., 2013, Stowell and Plumley, 2013]. [Lasseck, 2013] first pre-processed the recordings via the application of short-time Fourier transform, noise reduction and segmentation. Then, file-Statistics, segment-Statistics and segment-Probabilities are calculated as the features. Finally, for each sound class an ensemble of randomised decision trees is applied for the classification. [Stowell and Plumley, 2013] used either MFCC statistics (52 dimensions), chirplet histograms (up to

20,000 dimensions), or both, as the features. Then, Random Forests was applied for multi-label classification. [Mencía et al., 2013] proposed a new feature extraction method via an unsupervised generation of an aleatory number of features, which included random patching, a Denoising Autoencoder unit and subsequent convolution. For the classification, a pairwise ensemble of SVMs, random decision trees and a single layer neural network were used. [Massaron, 2013] described an approach that involved building an ensemble of generalised linear models and a classification model by hinge loss and program based on stochastic gradient descent optimisation, and boosted trees ensembles. [Chen et al., 2013] first calculated prominent features from windowing MFCCs with overlap, and leveraged them to build an ensemble classifier which was a blend of different classifiers (Gradient Boosting Tree models, Random Forest models, Lasso and elastic-net regularized generalised linear model .etc).

2.6 Experiment results with state-of-the-art methods

2.6.1 Evaluation criteria

Accuracy is the most widely used statistical criterion for evaluating frog call classification. Other evaluation criteria such as precision, recall, sensitivity, specificity, F-measure, and ROC curves are also used. Before defining these evaluation criteria, we first define true positives (TP), true negatives (TN), false negatives (FN), and false positives (FP) as described by [Gordon et al., 2003] (1) TP: correctly recognised positives; (2) TN: correctly recognised negatives; (3) FN: positives recognised as negatives; (4) FP: negatives recognised as positives. Then, accuracy, precision, recall (sensitivity), specificity, and false positive rate can be defined as

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (2.2)$$

$$Precision = \frac{TP}{TP + FP} \quad (2.3)$$

$$Recall = \frac{TP}{TP + FN} \quad (2.4)$$

$$Specificity = \frac{TN}{FP + TN} \quad (2.5)$$

$$FPR = \frac{FP}{FP + TN} \quad (2.6)$$

2.6.2 Previous experimental results

Table 2.3 shows the list of summarised frog call classification methods, together with the database they used and corresponding performance. From Table 2.3, we can find that few studies explored frog vocalisations using signal processing and machine learning techniques before 2010. Due to the decrease of frog biodiversity, advances in signal processing, machine learning techniques and acoustic sensors, the research in frogs has been increased in the last five years. In addition, few datasets are publicly shared with researchers. The classification performance of different studies varies a lot. One of the main reasons is the use of different datasets.

2.7 Research gap in current literature

In this section, the research gap of each part of a frog call classification system is discussed to give a direction for future work.

2.7.1 Database

One major problem for frog call classification is the lack of a universal database. The databases used are often related to geographical regions, since researchers from different countries focus on particular frog species in their specific area (Table 2.3). Therefore, it is difficult for researchers to compare their particular classification methods. Current studies often focus on the study of limited number of frog species (less than 100), but the number of known amphibian species is above 7000. To reach a high quality resolution, there still is a long way to go.

Table 2.3: A brief overview of frog call classification performance. The asterisk denotes that frog species are not the only animal species to be studied.

Database	Performance	Reference	Data source
3 frog species with 635 calls	Precision of 99%, recall of 92% Sensitivity of 0.85 with specificity of 0.92 when distinguishing <i>Miophytes literatus</i> calls from other species' call. Sensitivity of 0.88 with specificity of 0.82 against background noise	Camacho et al. [2011]	Collected from Costa Rica (unavailable)
1 frog species with 100 samples	50% true positive accuracy. over 50 false-negative for 4 animal types	Croker and Kotige [2012]	Recorded next to a running stream (unavailable)
17 animal types	NA	Brandoes et al. [2006]	Collected from NE Costa Rica (unavailable)
22 frog species	Best performance with averaged classification Accuracy of 72.18% and 0.76% for standard deviation.	Grigg et al. [1996]	Collected from Queensland, Australia (unavailable)
4 frog species with 66 samples	Accuracy of 88% for frogs	Yen and Fu [2002]	Unknown
10 frog species, 9 bird species, and 8 cricket species	Best true positive rate of 94.95% and 0.94% for false positive rate	Brandoes [2008]*	Collected from NE Costa Rica (unavailable)
9 frog species and 3 bird species with 10061 samples	Averaged classification accuracy of 90.00%	Acevedo et al. [2009]*	Collected from 14 montane sites in Puerto Rico
9 frog species with 90 syllables	Averaged classification accuracy of 98.00%	Dayou et al. [2011]	Obtained from http://www.Frogsaustralia.net.au/frogs
9 frog species with 54 syllables	Averaged classification accuracy of 95.86%	Han et al. [2011]	Obtained from http://www.Frogsaustralia.net.au/frogs
5 frog species with 727 syllables	Averaged classification accuracy of 95.86%	Huang et al. [2008]	Unknown
142 species belonging to four genera	Genus classification accuracy above 70%	Gingras and Fitch [2013]	obtained from commercially available compact discs (CDs) (available)
18 frog species with 960 syllables	Classification accuracy of 94.3%	Chen et al. [2012]	Recorded in a wild field located in the Shan-Ping forest ecological garden in Kaohsiung city, Taiwan (unavailable)
13 frog species with 1514 samples	Averaged recognition rate of 93.4%	Huang et al. [2014]	Unknown
5 frog species with 959 samples	Averaged classification accuracy of 90.03%	Huang et al. [2009]	Unknown
15 frog species with 286 samples	Averaged classification accuracy of 95.67%	Tan et al. [2014]	recorded at Sungai Sedim, in Kulim, Kedah, Malaysia
8 frog species with 160 samples	Averaged classification accuracy of 98.1%	Yuan and Ramli [2012]	Obtained from AmphibiaWeb (http://amphibiaweb.org/) (available)
10 frog species with 250 syllables	Averaged classification accuracy of 98.8%	Jaaifar et al. [2013a]	Internet database (http://learning.frogome.org/)
15 frog species with 386 syllables	Averaged classification accuracy of 85.78%	Jaaifar et al. [2013b]	IBM USM (http://www.frogwatch.org.au/?action=animalList) (available)
12 frog species with 291 syllables	Averaged classification accuracy of 97%	Jaaifar and Ramli [2013a]	Recorded from locations around Baling and Kulim, Kedah, Malaysia (unavailable)
12 frog species with 379 samples,	Averaged classification accuracy of 97%		Recorded from locations around Baling and Kulim, Kedah, Malaysia (unavailable)
10 bird species with 193 samples	Averaged classification accuracy of 86.6%	Vaca-Castano and Rodriguez [2010]	Recorded in Puerto Rico (http://www.amazon.com/Los-Anfibios-Reptiles-Puerto-Rico/dp/084770243X) (available)
13 frog species with 916 calls	Averaged classification accuracy of 100%, and 99.61% respectively for two database	Bedoya et al. [2014]	Provided by the Smithsonian Tropical Research Institute (STRI) and the Grupo Herpetológico de Antioquia (GHA) (unavailable)
30 frog species and 19 cricket calls	Averaged classification accuracy of 96.8% and 98.1%	Lee et al. [2006]	Derived from compact disk (unavailable)
15 frog species with 896 syllables	Precision of 99.00%	Coloma et al. [2015]	Obtained from Internet(http://bit.ly/1b8byE) (available)
10 frog species with 516 syllables	Averaged classification accuracy of 97.45%	Xie et al. [2013a]	Collected from compact disk (http://www.naturesound.com.au/) (available)
15 frog species with 436 syllables	Averaged classification accuracy of 74.73%	Xie et al. [2015c]	Collected from compact disk (http://www.naturesound.com.au/) (available)
9 frog species with 49 samples	Averaged classification accuracy of 97.60%	Coloma et al. [2012a]	Collected on the campus of the Federal University of Amazonas in Manaus, Brazil (unavailable)
3 frog species with 50 samples	Averaged classification accuracy of 90%	Dang et al. [2008]	Unknown
1564 syllables of 41 anurans,	98.8%, 96.9%, 95.48%, and 95.38% respectively	Noda et al. [2016]	AmphibiaWeb(41 anurans), 58 frogs from Cuba, 100 anurans from Brizil-Uruguay, and 199 anurans from all datasets (http://www.nihbs.com/) (available)
5201 syllables of 58 frogs,			
10905 syllables of 100 anurans,			
and 17671 syllables of 199 anurans			

2.7.2 Signal pre-processing

Currently, short-time Fourier transform (STFT) is the most widely used technique for frog call classification. However, STFT has a trade-off between time and frequency resolution, which restricts the discriminability of features extracted from the spectrogram. In contrast, wavelet

packet decomposition (WPD) has a better frequency domain resolution than STFT. The main disadvantage of WPD is the time dependence.

Noise reduction is an optional processing step in frog call classification. For some databases of studies shown in Table 2.3, frog calls have a high signal-to-noise ratio (SNR), where noise reduction is unnecessary. However, when studying recordings of low SNR, noise reduction is essential for improving the classification performance [Bedoya et al., 2014, Huang et al., 2014]. After noise reduction, both the accuracy of syllable segmentation and feature extraction can be relatively improved.

Frog syllable segmentation based on energy and zero-crossing rate cannot address recordings with low SNR. Meanwhile, this method cannot segment recordings with overlapping frog calls. Recent use of unsupervised learning algorithms opens a path for segmenting overlapping frog syllables with image processing techniques. However, like other unsupervised algorithms, this method has the disadvantage that not all segmented syllables are frog vocalisations [Potamitis, 2015]. Briggs et al used a supervised learning algorithm (Random Forest) for bird call segmentation. However, this method required lots of tagged acoustic data to train the classifier [Tjahja et al., 2015].

For syllable segmentation, time domain features are more sensitive to background noise than frequency domain features, because different frequency components can be separated by transforming the signal from time domain to frequency domain. But time domain features cannot segment those overlapping frog syllables, since time domain features have no ability to separate different frequency components. Compared to time domain features, the use of amplitude-frequency information provides a robust method to segment low SNR recordings. To address those overlapping frog syllables, image processing techniques can be a possible solution.

2.7.3 Acoustic features

Most previous studies directly transplant features developed for speech recognition to analyse frog calls, which might not be suitable. For example, MFCCs, which are based on the calculation of a non-linear Mel-scale, are designed for studying speech. However, the Mel-scale is designed for the perceptual scale of pitches judged by human listeners rather than frogs. The direct use of speech features will therefore restrict classification performance.

Most frequency domain features are calculated by directly calculating the statistics over frames, which leads to the loss of temporal information. To add the temporal information of the feature set, time domain features can be combined with frequency domain features to achieve higher classification accuracy. Transforming audio data into its two-dimensional representation (such as a spectrogram) for quick visual analysis, has led to increasing attention being given to image processing techniques for automatically analysing animal calls. Image features derived from spectrograms are worth investigating for frog call classification. Sparse coding has been widely applied for feature extraction in other scaled bioacoustics studies [Glotin et al., 2013, Razik et al., 2015], which could be a potential direction for frog call classification.

2.7.4 Classifiers

Almost all previous studies assume that each recording has only one frog species, and then a SISL classification framework is adopted to classify frog calls. However, recent advances in acoustic sensor techniques have collected large volumes of acoustic data that have multiple simultaneously vocalising frog species, because different frog species tend to call together to make a frog chorus (Figure 1.5). Based on this characteristic of frog call recordings, the classification problem can be naturally framed as a MIML classification or a ML classification problem rather than a SISL classification. In previous studies, MIML learning and ML learning have been used to solve bioacoustic problems, but mainly focus on birds. In this thesis, MIML and ML learning will be investigated to study frog vocalisations.

2.8 Summary

The main objective of this survey is to provide a research direction for analysing acoustic signals, especially frog calls. With the use of signal processing and machine learning techniques, different frog species can be classified based on their vocalisations. To achieve this goal, three main parts of a frog call classification system are explained: signal pre-processing, feature extraction, and classification. For each part, current techniques used by different researchers are explored. For signal pre-processing, signal processing, noise reduction, and syllable segmentation are studied respectively. For feature extraction, acoustic features in different domains are explored. For classification, different single-instance single-label classifiers are investigated.

In general, frog call classification is still in its infancy as a field of study, and potential applications and unsolved problems are extending every day. For future work, it is worth further improving the accuracy and efficiency of noise reduction and syllable segmentation because they are critical processes for frog call classification. Since collected frog calls in the field often contain many background noises (birds, insects, rain, wind, human voices, etc.), it is necessary to design new noise reduction methods based on different environments. It is also necessary to develop accurate and efficient methods for syllable segmentation for its great influence in the frog call classification system performance. Currently, studies have focused on frequency domain features for classification. In the future, time domain features can be more incorporated for increasing the accuracy of frog call classification. For the classification frameworks, using MIML learning or ML learning for studying environmental recordings may be a productive research direction because of the characteristic of collected acoustic data. It is also worth making a uniform dataset that covers different frog species from different areas, since there is still no available uniform dataset of frog calls. Then researchers can evaluate their particular methods on a uniform platform.

Chapter 3

Frog call classification based on enhanced features and machine learning algorithms

3.1 Overview

This chapter presents an enhanced feature set for frog call classification using various machine learning algorithms and explores whether a combination of three types of features discriminate a wider variety of species that may share similar characteristics in either temporal, perceptual or cepstral information but not all. In the literature, various feature sets have been developed for frog call classification. However, most features used in the prior work are based on either temporal features such as averaged energy and zero-crossing rate, perceptual features such as spectral centroid and spectral flux, or cepstral features such as MFCCs.

This chapter aims to compare various feature sets with different machine learning techniques. Based on the classification performance, suggested features can then be adapted to study low-SNR recordings. This chapter directly addresses sub-research question (1): How to improve the classification performance when addressing high SNR recordings. In particular, we want to know which of those features can be adapted from high SNR recordings to low SNR recordings, since our final goal of this thesis is to classify low SNR recordings.

The performance of the proposed method is evaluated based on twenty-four frog species, which are geographically well distributed through Queensland, Australia. Five feature sets are compared via five machine learning algorithms. Classification results demonstrate that a

combination of temporal, spectral and cepstral features can achieve the best performance. Compared with temporal and spectral features, cepstral features can achieve a robust classification accuracy, but are sensitive to the background noise. Therefore, in the next chapter, we aim to develop robust cepstral features that are not sensitive to the background noise.

3.2 Architecture of the classification system for frog calls

Our frog call classification system consists of six steps (Figure 3.1): data description, syllable segmentation, pre-processing, feature extraction, feature fusion, and classification. Detailed information of each step is shown in following subsections. Different from [Huang et al., 2009], pre-processing is directly applied to the segmented syllables rather than continuous recordings.

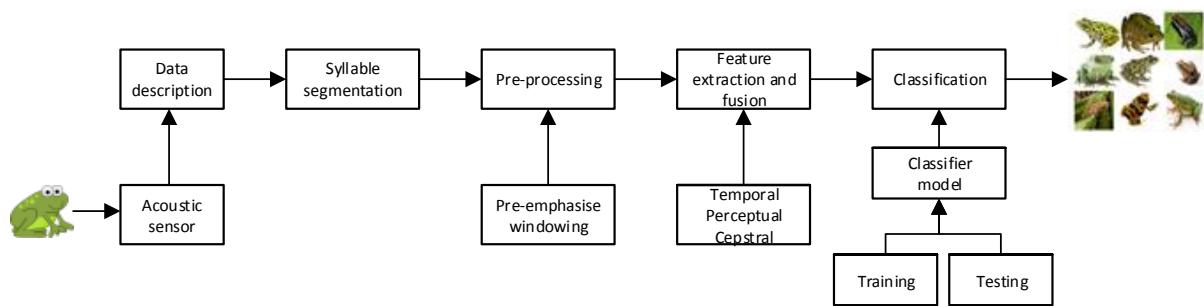

Figure 3.1: Flowchart of frog call classification system using enhanced features

3.2.1 Data description

In this study, twenty-four frog species, which are widespread in Queensland, Australia, are selected for experiments (Table 3.1). All the recordings are obtained from David Stewart's CD with a sample rate of 44.10 kHz and saved in MP3 format [Stewart, 1999]. Each recording includes one frog species with the duration ranging from eight to fifty-five seconds.

3.2.2 Syllable segmentation based on an adaptive end point detection

Each recording is made up of multiple continuous calls of one frog species. For frogs, one syllable is an elementary acoustic unit for classification, which is a continuous frog vocalisation emitted from an individual [Huang et al., 2009]. In this chapter, one method built on the Härmä's method is used to perform syllable segmentation for frog calls [Harma, 2003]. The

Table 3.1: Summary of scientific name, common name, and corresponding code. Frog species name with asterisk means that it needs to be smoothed before segmentation

No.	Scientific-name	Common-name	Code
1	<i>Assa darlingtoni</i>	Pouched frog	ADI
2	<i>Crinia parinsignifera</i>	Eastern sign-bearing froglet	CPA
3	<i>Crinia signifera</i>	Common eastern froglet	CSA
4	<i>Limnodynastes convexiusculus</i>	Marbled frog	LCS
5	<i>Limnodynastes ornatus</i>	Ornate burrowing frog	LOS
6	<i>Limnodynastes tasmaniensis</i> *	Spotted grass frog	LTS
7	<i>Limnodynastes terraereginae</i>	Northern banjo frog	LTE
8	<i>Litoria caerulea</i>	Australian green tree frog	LCA
9	<i>Litoria chloris</i>	Red-eyed tree frog	LCS
10	<i>Litoria latopalmata</i>	Broad-palmed frog	LLA
11	<i>Litoria nasuta</i>	Striped rocket frog	LNA
12	<i>Litoria revelata</i>	Revealed tree frog	LEA
13	<i>Litoria rubella</i>	Desert tree frog	LRA
14	<i>Litoria tyleri</i>	Southern laughing tree frog	LTI
15	<i>Litoria verreauxii verreauxii</i>	Whistling tree frog	LVI
16	<i>Mixophyes fasciolatus</i>	Great barred frog	MFS
17	<i>Mixophyes fleayi</i>	Fleay's barred Frog	MFI
18	<i>Neobatrachus sudelli</i> *	Painted burrowing frog	NSI
19	<i>Philoria kundagungan</i>	Mountain frog	PKN
20	<i>Philoria sphagnicola</i> *	Sphagnum frog	PSS
21	<i>Pseudophryne coriacea</i>	Red-backed toadlet	PCA
22	<i>Pseudophryne raveni</i> *	Copper-backed brood frog	PRI
23	<i>Uperoleia fusca</i> *	Dusky toadlet	UFA
24	<i>Uperoleia laevigata</i>	Smooth toadlet	ULA

syllable segmentation process is based on the spectrogram, which is generated by applying short-time Fourier transform (STFT) to each recording. For STFT, the window function used is Hamming window with the size and overlap being 512 samples and 25%, respectively. The detail of the segmentation method is described in Figure 3.2, which is based on the iterative frequency-amplitude information of the spectrogram. This chapter focuses on the evaluation of fused features, but the accuracy of segmentation results can greatly affect the classification performance. To reduce the bias introduced by syllable segmentation, the segmented syllables are further filtered. First, those syllables whose length are smaller than 300 samples are removed. Then, those syllables whose averaged energy is smaller than 15% of the maximum energy and

larger than 1.5 times the averaged energy are removed for each frog species experimentally [Gingras and Fitch, 2013].

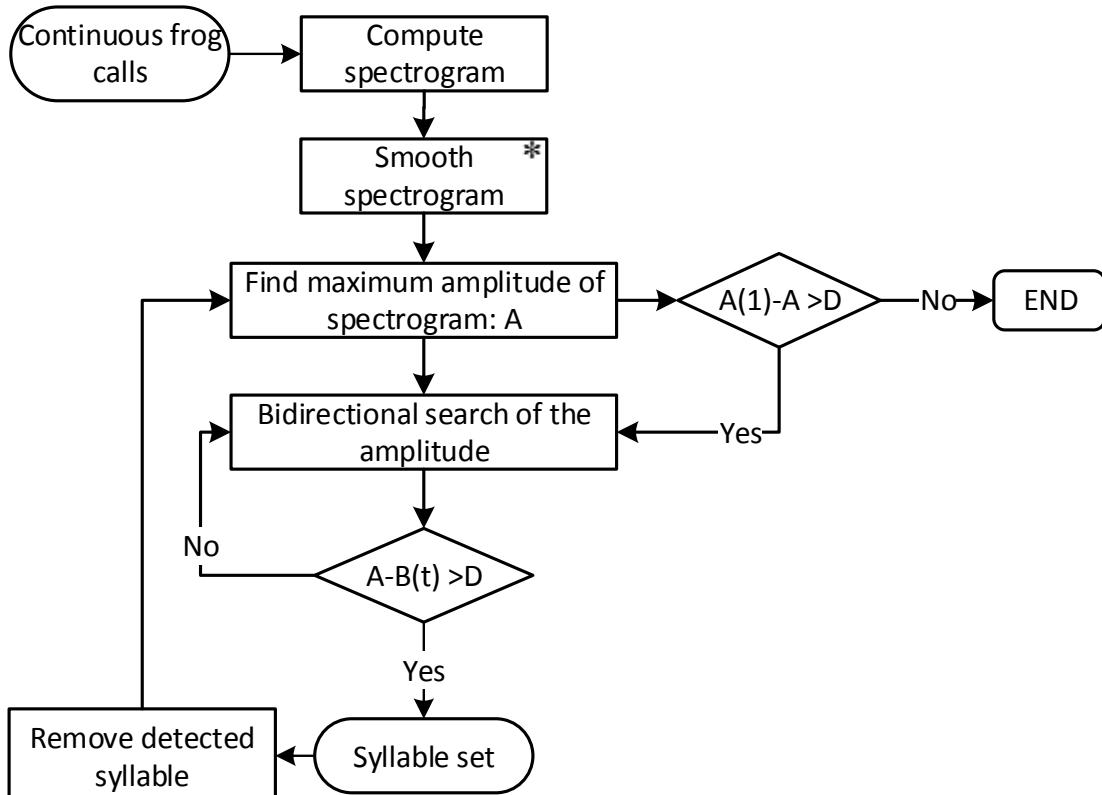

Figure 3.2: Segmentation method based on Härmä's algorithm. Here, D is the amplitude threshold for stopping criteria which is set at 20 dB experimentally, and the segmentation result is sensitive with this value. A is the maximum amplitude value of the spectrogram and we save the first maximum amplitude as $A(1)$, $B(t)$ is the amplitude of frame t . An asterisk denotes the optional processing step.

In this study, smoothing spectrogram is optionally applied to the spectrogram before the Härmä's algorithm, because some frog species have a large temporal gap within one syllable (see in Figure 3.3). As for the smoothing, a Gaussian filter (7×7) is applied to the spectrogram, where the size is set, taking into account a trade-off between connecting gaps within one syllable and separating adjacent syllables. The segmentation result after smoothing is shown in Figure 3.3. The distribution of syllable numbers after segmentation for all frog species is shown in Figure 3.4.

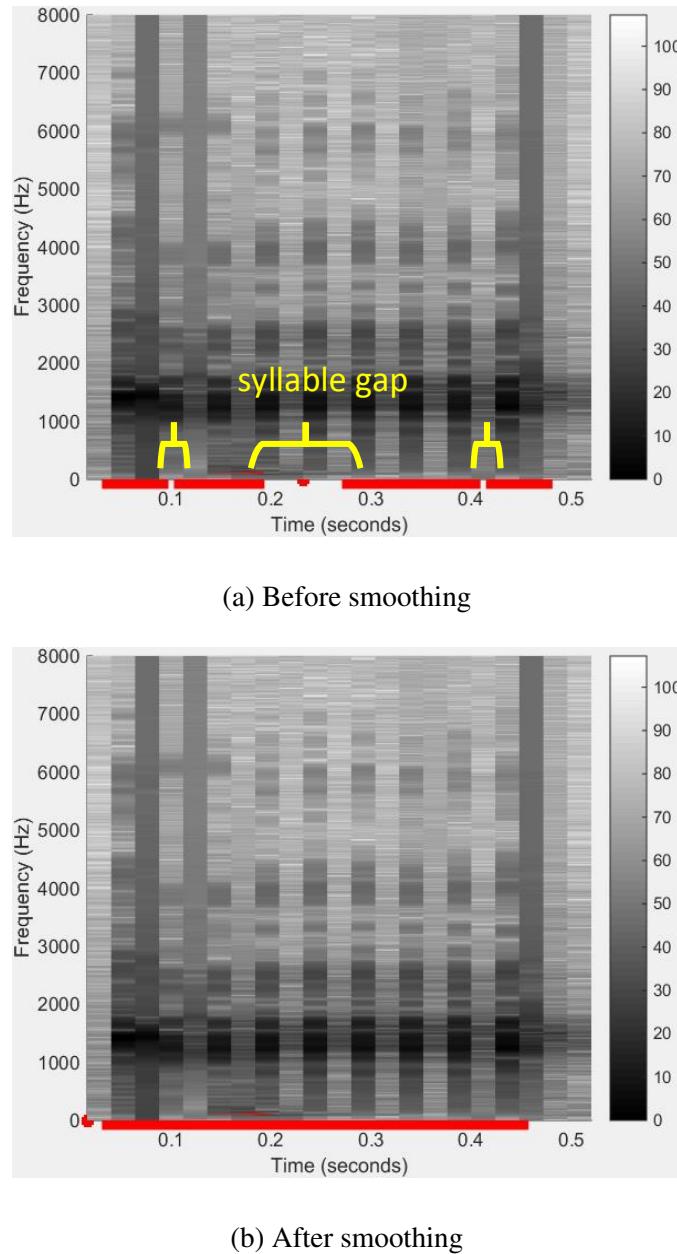

Figure 3.3: Syllable segmentation results are marked with a red line for *Neobatrachus sudelli* (one syllable).

3.2.3 Pre-processing

Since features play an important role in the classification performance, pre-processing is applied to each syllable to improve the accuracy of feature extraction. The pre-processing of each syllable consists of the following steps:

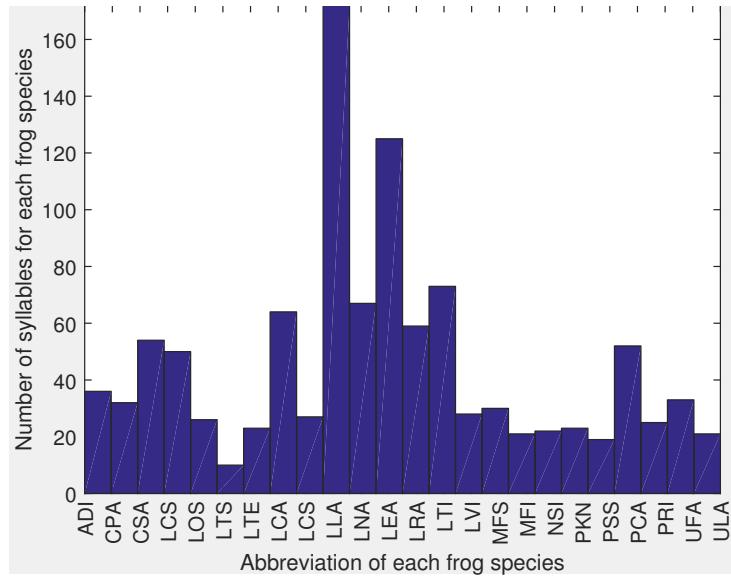

Figure 3.4: Distribution of syllable number for all frog species. The x-axis is the abbreviation of each frog species, and the corresponding scientific name can be found in Table 3.1.

Pre-emphasis

Some collected frog calls have low amplitude but in the high frequency, which will have an effect on feature extraction of the spectrum at the high frequency end. To enhance those high-frequency components and reduce the low-frequency components, a first-order high-pass filter with finite impulse response (FIR) is introduced and defined as

$$y(n) = s(n) - \alpha s(n-1) \quad (3.1)$$

where s denotes a frog syllable, y is the output of the high-pass filter, α denotes the cut-off frequency of the high-pass filter and is set at 0.97 here, n is the n-th sample of the syllable.

Windowing

After pre-emphasis, each syllable is segmented into overlapping frames with fixed length. A Hamming widow is used to minimise the maximum side-lobe in the frequency domain and get side-lobe suppression, which is defined as

$$w(n) = 0.54 - 0.46\cos\left(\frac{2n\pi}{L-1}\right), 0 \leq n \leq L-1 \quad (3.2)$$

where L is the length of the frame. Because window sizes have an effect on the classification results, different window sizes are optimised for different features in this study. The signal after windowing process is expressed as

$$x(n) = w(n)y(n) \quad (3.3)$$

3.2.4 Feature extraction

After pre-processing of each syllable, various parametric representations are used to represent the syllable. In the literature, a variety of parametric representations of frog calls can be found, such as LPCs and MFCCs [Bedoya et al., 2014, Jaafar and Ramli, 2013b, Yuan and Ramli, 2012]. MFCCs achieved a better performance than LPCs [Yuan and Ramli, 2012]. Different from the hybrid features used [Gingras and Fitch, 2013, Han et al., 2011, Huang et al., 2009], our enhanced feature consists of more features, such as oscillation rate [Xie et al., 2015b], to further improve the classification accuracy. In this study, temporal features include syllable duration, Shannon entropy, rényi entropy, zero-crossing rate, averaged energy, and oscillation rate. Perceptual features contains spectral centroid, spectral flatness, spectral roll-off, signal bandwidth, spectral flux, and fundamental frequency. Here the word *perceptual* is defined according to [Lei et al., 2014]. MFCCs are used as a cepstral feature. The description of each feature is listed below.

(1) Syllable duration: Syllable duration [Xie et al., 2015b] is directly obtained from the bounds (time domain) of the segmentation results.

$$Dr = x(n_e) - x(n_s) \quad (3.4)$$

where n_e and n_s are the end and start location of one segmented syllable.

(2) Shannon entropy: Shannon entropy is the expected information content of a sequence of a signal. It is often used to describe the average of all the information contents weighted by their probabilities p_i .

$$Se = - \sum_{i=1}^L p_i \log_2(p_i) \quad (3.5)$$

where L is the length of a frog syllable.

(3) Rényi entropy: rényi entropy is calculated to obtain the different averaging of probabilities via the parameter α , and defined as

$$Re = \frac{1}{1 - \alpha} \log_2 \left(\sum_i^n p_i^\alpha \right) \quad (3.6)$$

where p_i is the probabilities of the occurrence $x(n)$ in the signal.

(3) Zero-crossing rate: zero-crossing rate denotes the rate of signal change along a signal. When adjacent signals have different signs, a zero-crossing occurs. The mathematical expression of ZCR can be defined as

$$Zcr = \frac{1}{2} \sum_{n=0}^{L-1} [sgn(x(n)) - sgn(x(n + 1))] \quad (3.7)$$

(4) Averaged energy: Averaged energy is defined as the sum of intensity of signal.

$$Ae = \frac{1}{L} \sum_{n=0}^{L-1} x(n)^2 \quad (3.8)$$

(5) Oscillation rate: Oscillation rate is calculated in the frequency boundary around the fundamental frequency. First, the power within the frequency boundary is calculated. After normalising the power, the first and last 20% part of the power vector is discarded due to the uncertainty. Next, the autocorrelation is performed by the length of the vector. Furthermore, a discrete cosine transform is employed to the vector after mean subtraction, and the position of the highest frequency is achieved to calculate the oscillation rate.

(6) Spectral centroid: spectral centroid is the centre point of spectrum distribution. In terms of human audio perception, it is often associated with the brightness of the sound. With the magnitudes as the weight, it is calculated as the weighted mean of the frequencies.

$$Sc = \frac{\sum_{k=0}^{N-1} f_k X(k)}{\sum_{k=0}^{N-1} X(k)} \quad (3.9)$$

where $X(k)$ is the discrete Fourier transform (DFT) of the syllable signal of the k-th frame, N is the half size of DFT.

(7) Spectral flatness: spectral flatness provides a way to quantify the tonality of a sound. A higher spectral flatness indicates a similar amount of power of the spectrum in all spectral bands. Spectral flatness is measured by the ratio between the geometric mean and the arithmetic mean of the power spectrum and defined as

$$Sf = \frac{\exp\left(\frac{1}{N} \sum_{k=0}^{N-1} \ln X(k)\right)}{\frac{1}{N} \sum_{k=0}^{N-1} X(k)} \quad (3.10)$$

(8) Spectral roll-off: spectral roll-off is often used to measure the spectral shape, and defined as the frequency H . Here H is the value below which the θ of the magnitude distribution is concentrated.

$$\sum_k^H X(k) = \theta \sum_{k=1}^{N-1} X(k) \quad (3.11)$$

where θ is set at 0.85.

(9) Signal bandwidth: signal bandwidth can be used to represent the difference between the upper and lower cut-off frequencies.

$$Bw = \sqrt{\frac{\sum_{k=0}^{N-1} (k - Sc)^2 |x(n)|}{\sum_{k=0}^{N-1} X(k)}} \quad (3.12)$$

(10) Spectral flux: spectral flux is used to measure how quickly the power spectrum of a signal is changing. The spectral flux can be obtained via the power spectrum comparison between one frame and its previous one. The calculation of spectral flux is denoted as

$$Sf = \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} H[|X(n, k)| - |X(n - 1, k)|] \quad (3.13)$$

where $H(x) = (x + |x|)/2$ is a half-wave rectifier function.

(11) Fundamental frequency: fundamental frequency is calculated via averaging peak intensity of all frames within one frog syllable. If the peak intensity value is higher than an empirically chosen or specified threshold, the frequency of that peak will be selected to calculate the fundamental frequency.

(12) Mel-frequency cepstral coefficients (MFCCs): MFCCs, which are obtained by applying cosine transform to a sub-band Mel-frequency spectrum within a short time, have been widely used in bird classification [Lee et al., 2006], speech/speaker recognition [Han et al., 2006], and frog identification [Bedoya et al., 2014]. In this study, MFCCs are calculated based on the method of [Lee et al., 2006].

Step 1: Band-pass filtering: The amplitude spectrum is then filtered using a set of triangular band-pass filters.

$$E_j = \sum_{k=0}^{N/2-1} \phi_j(k) A_k, 0 \leq j \leq J-1 \quad (3.14)$$

where J is the number of filters, ϕ_j is the j^{th} filter, and A_k is the amplitude of $X(k)$.

$$A_k = |X[k]|^2, 0 \leq k \leq N/2 \quad (3.15)$$

Step 2: Discrete cosine transform: MFCCs for the i^{th} frame are computed by performing DCT on the logarithm of E_j .

$$C_m^j = \sum_{j=0}^{J-1} \cos\left(m \frac{\pi}{J}(j + 0.5)\right) \log_{10}(E_j), 0 \leq m \leq L-1 \quad (3.16)$$

where L is the number of MFCCs.

In this study, the filter bank consists of 40 triangular filters, that is $J = 40$. The length of MFCCs of each frame is 12 ($L=12$). After calculating MFCCs from each frame, the averaged MFCCs of all frames within one syllable are calculated as

$$f_m = \frac{\sum_{i=1}^K (C_m^i)}{K}, 0 \leq m \leq L-1 \quad (3.17)$$

where f_m is the m^{th} MFCCs, K is the number of frames within the syllable.

For all perceptual features and Zcr , the mean values are calculated to characterise the frog syllable. Then, the L -dimensional MFCC vectors are fused with the other 11 feature vectors to form the enhanced temporal, perceptual and cepstral (TemPerCep) features.

After the formulation of feature vectors, normalisation is conducted as

$$v_i = \frac{v_i - \mu_i}{\sigma_i} \quad (3.18)$$

where μ_i and σ_i are the mean and standard deviation computed for each feature vector i .

Let F_1 represent temporal features with length L_1 , F_2 and F_3 represent perceptual features and cepstral features with length L_2 and L_3 , respectively. The enhanced procedure is performed as

$$F_H = w_1 F_1 \oplus w_2 F_2 \oplus w_3 F_3 \quad (3.19)$$

where w_1 , w_2 , and w_3 are the weights, \oplus is the concatenation operation.

3.2.5 Classifier description

In this chapter we report the results for five classification algorithms: 1) Linear discriminant analysis (LDA), 2) K-nearest neighbour, 3) Support vector machines, 4) Random forest, 5) Artificial neural network. Five feature vectors, LPCs, MFCCs, enhanced temporal feature and MFCCs (*TemCep*), enhanced temporal and perceptual features (*TemPer*), enhanced temporal, perceptual features, and MFCCs (*TemCepPer*), are fed into each classifier respectively to test their classification performance.

Linear discriminant analysis

After transforming the feature vector into low-dimensional space, the classification accuracy can be improved for linear discriminant analysis (LDA). In LDA, the goal is to find an optimal transformation matrix to transform the feature vector from an n-dimensional space to a d-dimensional space. A linear mapping, which maximises the Fisher criterion J_F , is used to obtain the transformation matrix as

$$J_F(A) = \text{tr}((A^T S_w A)^{-1} (A^T S_B A)) \quad (3.20)$$

where S_w and S_B are the within-class scatter matrix and between-class scatter matrix, respectively. The within-class scatter matrix and between-class scatter matrix are respectively defined as

$$S_W = \sum_{j=1}^C \sum_{i=1}^{N_j} (F_i^j - \mu_j)(F_i^j - \mu_j)^T \quad (3.21)$$

$$S_B = \sum_{j=1}^C (\mu_i - \mu)(\mu_i - \mu)^T \quad (3.22)$$

where F_i^j is the i-th feature vector of frog species j , μ_j is the mean vector of species j , C is the number of frog species, and N_j is the number of feature vectors in species j , μ is the mean vector of all frog species.

The optimisation of the transform matrix can be determined via finding the eigenvectors of $S_W^{-1} S_B$.

$$A_{opt} = \operatorname{argmax} \frac{\operatorname{tr}(A^T S_B A)}{A^T S_W A} \quad (3.23)$$

In the recognition stage, the feature vector is first transformed into a lower-dimensional space via A_{opt} derived by LDA. Then, the distance between the feature vector of the test syllable and the feature vector representing this species is calculated. The one with minimum distance is regarded as the identified species.

K-nearest neighbour

For the kNN classifier, the distance between an input frog feature vector and all stored feature vectors is first calculated. Then K closest vectors are selected to determine the species of the input feature vector by majority voting. For example, the Euclidean distance between an input instance i (frog feature vector) and one stored instance j is calculated as

$$d(i, j) = \sqrt{\sum_{c=1}^n (F_{i,c} - F_{j,c})^2} \quad (3.24)$$

Then the species of this input instance i can be predicted from the selected k nearest neighbours.

If

$$\frac{1}{k_1} \sum_{j \in S_1} d(i, j(S_1)) \leq \frac{2}{k_2} \sum_{j \in S_2} d(i, j(S_2)) \quad (3.25)$$

where $k = k_1 + k_2$, k_1 is the number of frog species S_1 , k_2 is the number of frog species S_2 . Here the input instance i will be classified as frog species S_2 . Following prior work ([Han et al.,

2011, Xie et al., 2015b]), the distance function used for kNN is the Euclidean function, and k is set at 1.

Support vector machines

Due to the high accuracy and superior generalisation properties, support vector machines (SVM) have been widely used for classifying animal sounds [Huang et al., 2009] [Acevedo et al., 2009]. In this study, the feature set obtained is first selected as training data. Then, the pairs $(F_l^n, L_l^n), l = 1, 2, \dots, C_l$ are constructed using the selected training data, where C_l is the number of frog instances in the training data, F_l^n is the feature vector obtained from the l -th frog instance in the training data, L_l^n is the frog species label. Furthermore, the decision function for the classification problem based on SVM [Cortes and Vapnik, 1995] is defined by the training data as

$$f(v) = \operatorname{sgn}\left(\sum_{sv} \alpha_l^n L_l^n K(v, v_l^n) + b_l^n\right) \quad (3.26)$$

where $K(., .)$ is the kernel function, α_l^n is the Lagrange multiplier, and b_l^n is the constant value. In this work, the Gaussian kernel is selected as the kernel function. Parameters α and v are selected independently for each feature vector by grid search using cross-validation [Hsu et al., 2003].

Random forest

Random forest (RF) is a tree-based algorithm, which builds a specified number of classification trees without pruning. The nodes are split on a random drawing of m features from the entire feature set M . A bootstrapped random sample from the training set is used to build each tree. The advantage of RF is its ability to generate a metric to rank predictors based on their relative contribution to the model's predictive accuracy [Bao and Cui, 2005]. The prediction is defined as

$$\operatorname{Pred} = \frac{1}{K} \sum_{n=1}^K T_i \quad (3.27)$$

where T_i is the n-th tree response of the RF. In this work, the number of trees K is set at 300 trees to characterise frog calls. As for the predictor variables m , it is set at \sqrt{N} , where N is the feature dimension in a syllable.

Artificial neural network

Artificial neural network (ANN) is a non-linear, adaptive, machine learning tool with great capabilities for learning, generalisation, non-linear approximation, and classification. An ANN architecture often consists of many interconnected neurons organised in successive layers: pattern layer, summation layer, and decision layer. The neuron in class is often computed by a Gaussian function. Then, the summation layer uses summation units to memorise the class conditional probability density functions of each class through a combination of Gaussian densities. Lastly, the decision layer unit classifies the pattern in accordance with the Bayesian decision rule based on the output of all summation layer neurons as

$$D(F) = \text{argmax} p_i(F), i = 1, \dots, N \quad (3.28)$$

where i is the species index, N is the total number of frog species.

$$p_i(F) = \sum_{j=1}^{m_i} \beta_{ij} \phi_{ij}(F) \quad (3.29)$$

where m_i is the number of Gaussian components, β_{ij} and $\phi_{ij}(F)$ can be represented as

$$\sum_{j=1}^{m_i} \beta_{ij} = 1 \quad (3.30)$$

$$\phi_{ij}(F) = \frac{1}{(2\pi)^{(d/2)} \sigma^d} \exp\left[-\frac{(F - \mu_{ij})^T (F - \mu_{ij})}{2\sigma^2}\right] \quad (3.31)$$

where $i = 1, \dots, N$, $j = 1, \dots, m_i$, d denotes the dimension of the input vector F , σ is the smoothing parameter, μ_{ij} is the mean vector and the central of the classification. In this study, one ANN classifier named multiple perception layer (MLP) is used to classify frog calls.

3.3 Experiment results

In this experiment, performance statistics is evaluated using 5-fold cross-validation. The performance of the proposed frog call classification system is evaluated by quantitatively expressed

detection metrics, such as average accuracy, precision, and specificity. The definition of accuracy, precision, and specificity can be found in Chapter 2.6.

3.3.1 Effects of different feature sets

Figure 3.5 illustrates the classification accuracy with different feature sets: LPCs, MFCCs (*Cep*), temporal features and MFCCs (*TempCep*), temporal features and perceptual features (*TemPer*), and temporal features, perceptual features and MFCCs (*TemPerCep*). It can be seen that cepstral features (*Cep*, *TempCep*, *TemPerCep*) have a more stable performance than LPCs and perceptual features. It is evident that our proposed enhanced feature (*TemPerCep*) shows outstanding performance of all proposed feature sets of all the machine learning techniques. The reason for the high classification accuracy is that frog calls are of short duration and cover a small spectral band. Our proposed enhanced feature, *TemPerCep*, can better characterise the content of frog calls. Although the classification performance of *TemPerCep* is not significantly higher than other feature sets, the difference does show that our proposed feature set is suitable and effective for the classification of frog calls.

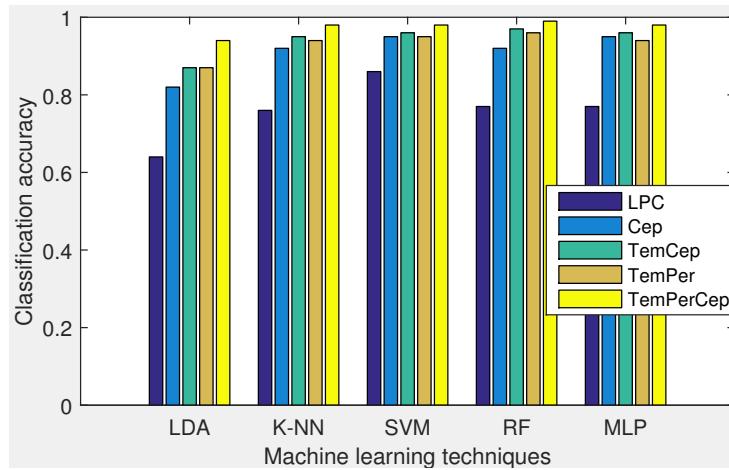

Figure 3.5: Classification results with different feature sets using the window size of 64 samples

3.3.2 Effects of different machine learning techniques

Figure 3.6 shows the frog call classification performance of *TemPerCep* with different machine learning techniques. The high classification results in term of the accuracy, sensitivity and specificity measure of different classifiers indicates good classification performance. It can be observed that RF achieves the best classification performance, while the classification

performance of LDA is the lowest. Meanwhile, the classification performances of SVM and MLP are very good, which might be that the features and classifiers are quite suitable. It can be seen from Figure 3.6 that frog call classification with different machine learning techniques can achieve good performance with our enhanced feature set, because the classification accuracy is very high. It can also be noted that RF can be highly recommended for classification of frog calls due to the highest classification accuracy.

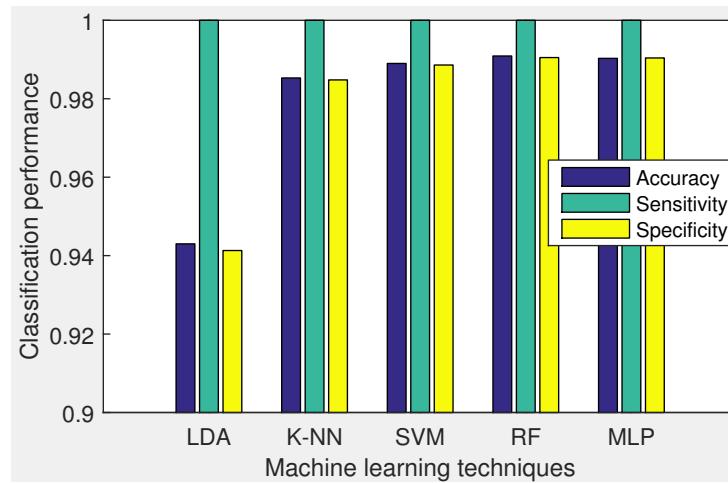

Figure 3.6: Results of different classifiers

3.3.3 Effects of different window size for MFCCs and perceptual features

As we know, the window size has an effect on the MFCCs and perceptual features. Therefore, a different window size will lead to a different classification performance (Figure 3.7 and Figure 3.8). The window size used for the test is 32, 64, 128, 256, because the syllable length of some frog species is less than 512 samples. It is found that the best classification performance for MFCCs is achieved with window size of 64 samples. For *TemPer*, the window size of 64 obtains the best classification performance. It also can be observed that SVM and RF achieve the best classification performance. Moreover, different window sizes of MFCCs have a larger variation than *TemPer* features, which might be because temporal features have a high weight in *TemPer* for the classification task.

3.3.4 Effects of noise

To further evaluate the robustness of our proposed feature set, white noise with different signal-to-noise (SNR) of 40 dB, 30 dB, 20 dB, 10 dB, 0dB, and -10 dB is added to the frog calls.

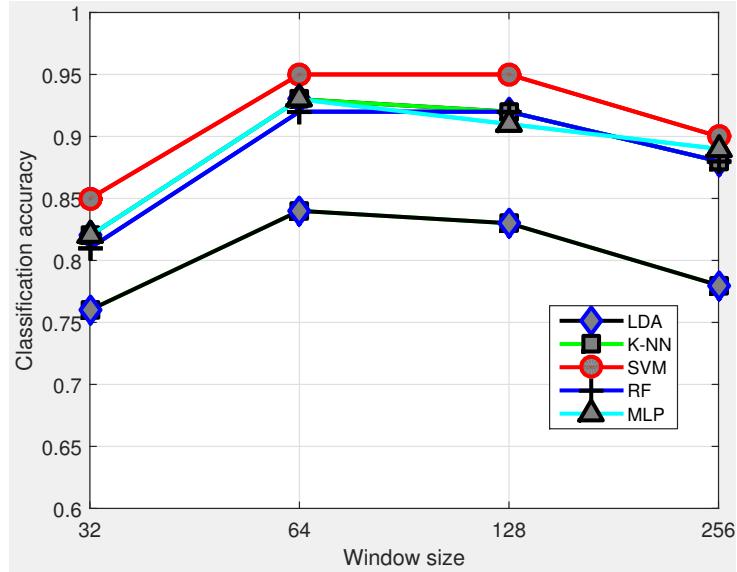

Figure 3.7: Classification results of MFCCs with different window sizes

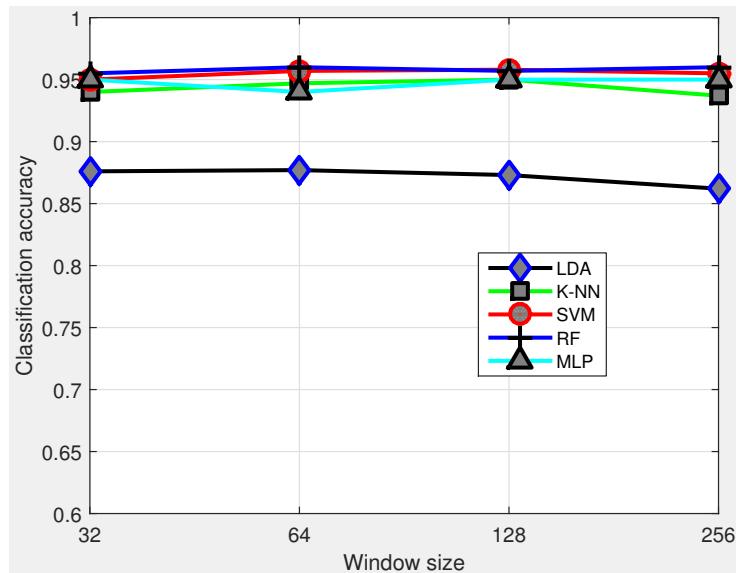

Figure 3.8: Classification results of TemPer with different window sizes

Because this chapter focuses on the evaluation of features rather than the segmentation method, the artificial noise is added after syllable segmentation. Since SVM has shown a good performance for frog call classification in 3.3.1, we only use SVM to test the effects of different levels of artificial noise. The classification results of different levels of noise contamination are shown in Figure 3.9. It is found from Figure 3.9, that MFCCs (Cep) are very sensitive to background noise, compared with other feature sets. Comparing *TemCep* with *TemPer*, it can be observed that perceptual features have a better anti-noise ability than the cepstral feature. It is also found that LPCs have a good anti-noise ability when SNR is larger than 10, but the classification accuracy quickly decreases when SNR is smaller than 10.

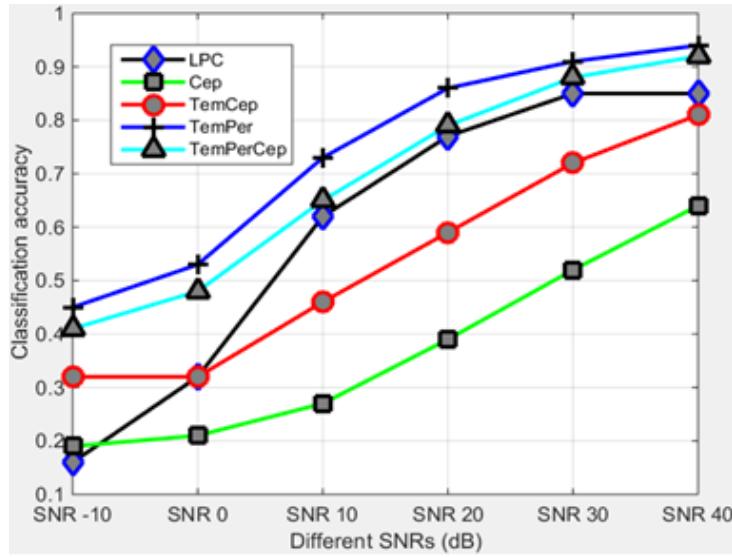

Figure 3.9: Sensitivity for different features for different levels of noise contamination

3.4 Discussion

Table 3.2 shows the classification performance of previous methods. Since previous studies often used different datasets to perform the classification task, this research implemented all those features and applied them to the used dataset with the same classifier (SVM). Compared with those previous methods, this proposed enhanced feature set significantly outperforms other methods. Therefore, it can be concluded that the results of this research stand above the current classification performance. From the table, we can also observe that MFCCs are the most popular feature that has been used for frog call classification. Among all used machine learning techniques, SVM shows the superior performance and is widely used for the classification task. It can be found that the classification accuracy of *TemPerCep* does not show significant improvement when compared with MFCCs. However, combining temporal and perceptual features with cepstral features greatly improves the anti-noise ability of MFCCs.

3.5 Summary and limitations

In this chapter, a novel enhanced feature set was proposed to classify frog calls with various machine learning techniques. After segmenting continuous recordings into individual syllables, a variety of acoustic features are extracted from each syllable. Then, different features are combined to form different feature sets. Finally, various machine learning techniques are used to classify frog calls with different feature sets. Our proposed enhanced feature set shows

Table 3.2: Comparision with previous used feature sets

Ref.	Feature	Accuracy
[Juan Mayor, 2009, Yuan and Ramli, 2012]	LPCs	93.5%
[Bedoya et al., 2014, Jaafar and Ramli, 2013b, Lee et al., 2006, Xie et al., 2015b]	MFCCs	94.9%
[Han et al., 2011]	Spectral centroid, Shannon entropy, Rényi entropy	75.6%
[Xie et al., 2015b]	Syllable duration, dominant frequency, oscillation rate, frequency modulation, energy modulation	92.3%
[Huang et al., 2014]	Spectral centroid, signal bandwidth, spectral roll-off, threshold-crossing rate, spectral flatness, and average energy	95.8%
Our feature set	<i>TemPerCep</i>	99.1%

the best classification accuracy and has good anti-noise ability. Meanwhile, the SVM and RF outperform the traditional LDA and kNN classifiers. Therefore, it is suitable to combine *TemPerCep* with SVM or RF to build a frog call classification system. Ecologists can apply the proposed classification system to long-term frog recordings. Then, the long-term change of frog species richness can be reflected by the classification results.

Since the MFCCs feature shows a good classification performance, but a bad anti-noise ability, we can modify MFCCs to improve the anti-noise ability. After transforming frog audio data into its spectrogram representation, the visual inspection motivates us to use image processing techniques for studying frog calls. Also, a wider variety of frog audio data from different geographical and environmental conditions will be tested in future experiments.

Chapter 4

Adaptive frequency scaled wavelet packet decomposition for frog call classification

4.1 Overview

This chapter presents a novel cepstral feature based on adaptive frequency scaled wavelet packet decomposition. Following the conclusion of Chapter 3 that cepstral features can achieve a good classification accuracy, but are sensitive to background noise, the goal of this chapter is to develop a novel cepstral feature with a good anti-noise ability.

Since both high and low SNR recordings are studied in this research, developing features with a good anti-noise ability is important for dealing with low SNR recordings. Different from most previous studies that extracted features via the Fourier transform, wavelet packet decomposition is employed in this chapter for feature extraction. The classification performance is evaluated with two different datasets from Queensland, Australia (18 frog species from commercial recordings (high SNR) and field recordings of eight frog species from James Cook University recordings (low SNR)). This chapter answers research question 2: How to improve the performance of developed features for frog call classification in low SNR recordings?

Although low SNR recordings are used in this research, the classification task is regarded as a single-instance single-label learning problem. However, most individual low SNR recordings have more than one frog species. In the next two chapters, we will focus on the classification of multiple simultaneously vocalising frog species in one individual recording.

4.2 Method

The architecture of the proposed classification method consists of five modules: syllable segmentation, syllable feature extraction, adaptive frequency scale generation, WPD feature extraction and classification (see Figure 4.1). Each module is described in the following sections.

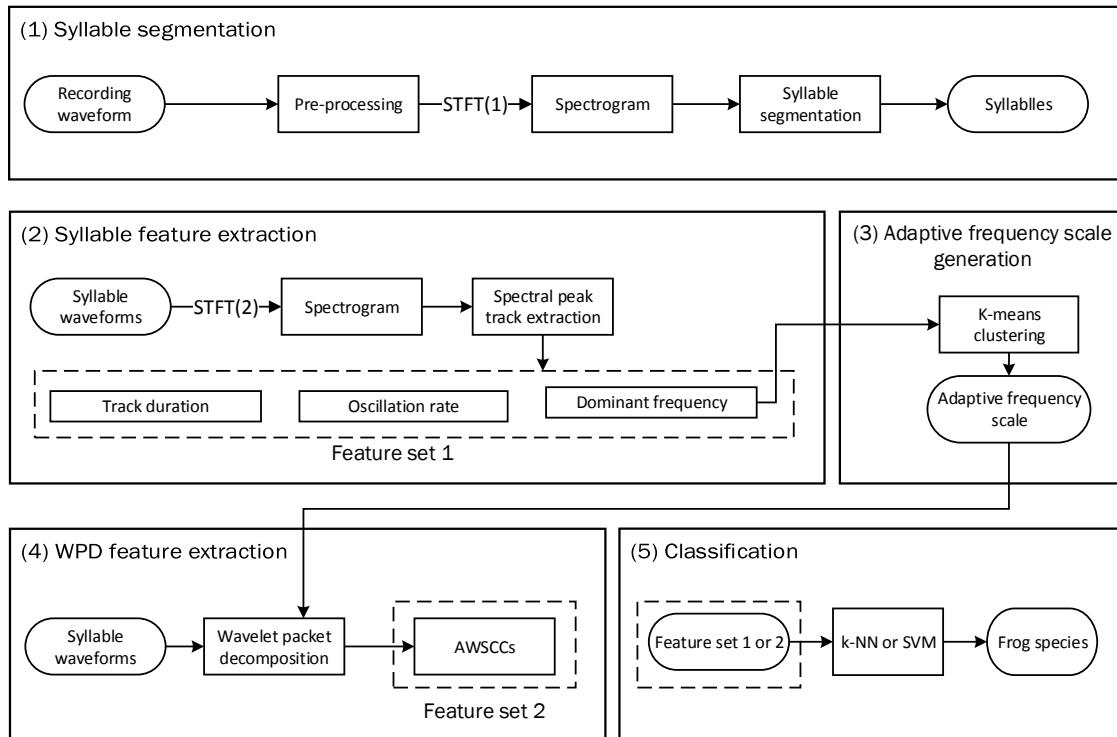

Figure 4.1: Block diagram of the frog call classification system. The line of dashes indicates the extracted feature set. AWSCCs is the abbreviation of *adaptive wavelet packet decomposition sub-band cepstral coefficients*. STFT is short-time Fourier transform. For STFT(1), the window function, size and overlap are Kaiser window, 512 samples and 25%. For STFT(2), the window function, size and overlap are Hamming window, 128 samples and 90%. In this diagram, two feature sets are extracted, the description of other feature sets is shown in Figure 4.6.

4.2.1 Sound recording and pre-processing

Two datasets obtained from a commercial recording [Stewart, 1999] and James Cook University (JCU) were selected for this chapter. Recordings, which were collected from the CD, are two-channel, sampled at 44.10 kHz and saved in MP3 format. All recordings were obtained with a directional microphone and have a high signal to noise ratio (SNR). Each recording includes one frog species, and has a duration ranging from twenty-one to fifty-four seconds. The calls of eighteen frog species recorded in Queensland, Australia were used to develop the detailed

methodology described in Figure 4.1. To reduce the subsequent computational burden, all the recordings selected from the CD were re-sampled at 16 kHz per second, mixed to mono, and saved in WAV format.

The JCU recordings were obtained from Kiyomi dam (S 19° 22' 16.0'', E 146° 27' 31.3'') BG Creek dam (S 19° 27' 1.23'', E 146° 24' 5.65'') and Stony Creek dam (S 19° 24' 07.0'', E 146° 25 51.3) in Townsville, using Song Meter (SM2) [Xie, 2016]. The recordings were stored on 16 GB SD cards in 64 kbps MP3 mono format and have a low SNR compared with the commercial recording. The sample rate is 16.00 kHz. All the JCU recordings started around sunset, finished around sunrise every day and have 12 hour duration.

4.2.2 Spectrogram analysis for validation set

In this chapter, three syllables for each frog species are set aside and used as a *reference data set*. For the commercial recording, three parameters including syllable duration, dominant frequency, and oscillation rate, are manually calculated for those three syllables of each species and averaged, as listed in Table 4.1. The reference data set is excluded from the data used in the testing stage.

Table 4.1: Parameters of 18 frog species averaged of three randomly selected syllable samples in the commercial recording. These selected samples make the *reference data set*.

No.	Scientific name	Abbreviation	Syllable duration (millisecond)	Peak frequency (Hz)	Oscillation rate (cycle/second)
1	Assa darlingtoni	ADI	80	3200	160
2	Crinia parinsignifera	CPA	250	4300	350
3	Litoria caerulea	LCA	500	500	50
4	Litoria chloris	LCS	800	1700	220
5	Litoria fallax	LFX	430	4700	70
6	Litoria gracilenta	LGA	1400	2700	100
7	Litoria latopalmata	LLA	30	1400	2100
8	Litoria nasuta	LNA	100	2800	160
9	Litoria revelata	LRA	160	4100	70
10	Litoria rubella	LUA	500	2900	60
11	Litoria verreauxii verreauxii	LVV	270	3100	125
12	Mixophyes fasciolatus	MFS	200	1200	140
13	Mixophyes fleayi	MFI	50	1000	140
14	Philoria kundagungan	PKN	170	430	95
15	Pseudophryne coriacea	PCA	300	2400	80
16	Pseudophryne raveni	PRI	370	2500	45
17	Rheobatrachus silus	RSS	510	1500	60
18	Uperoleia laevigata	ULA	450	2400	150

For the JCU recordings², the corresponding parameters are described in Table 4.2. Compared with the commercial recordings from the CD, peak frequency shows a smaller variation than syllable duration and oscillation rate.

Table 4.2: Parameters of eight frog species obtained by averaging three randomly selected syllable samples from recordings of James Cook University. NA indicates there is no oscillation structure in the spectrogram for the background noise and frog chorus. Since syllable durations of *Rhinella marina* (Common name: Canetoad) are very different from each other, we manually set the duration of Canetoad using the maximum duration of other frog species, which is 500 milliseconds.

No.	Scientific name	Abbreviation	Syllable duration (millisecond)	Peak frequency (Hz)	Oscillation rate (cycles/second)
1	<i>Rhinella marina</i>	CTD	500	680	12
2	<i>Cyclorana novaehollandiae</i>	CNE	350	600	NA
3	<i>Limnodynastes terraereginae</i>	LTE	80	630	NA
4	<i>Litoria fallax</i>	LFX	120	4100	50
5	<i>Litoria nasuta</i>	LNA	100	2700	NA
6	<i>Litoria rothii</i>	LRI	350	1150	15
7	<i>Litoria rubella</i>	LUA	500	2400	NA
8	<i>Uperoleia mimula</i>	UMA	120	2400	40

4.2.3 Syllable segmentation

The syllable segmentation process is described in Chapter 3.2.2. To further improve the segmentation result, the averaged energy of which is less than 15% of the maximum energy, are removed [Gingras and Fitch, 2013]. The distribution of syllable numbers after segmentation for all frog species is shown in Figure 4.2.

For the JCU recordings, bandpass filtering is applied to each recording before using the Härmä's method [Harma, 2003]. A bandpass filter is first used to filter specific frog species, because different frog species tend to call simultaneously. The filtering is

$$S'(t, f) = \begin{cases} S(t, f) & F_{lower} \leq f \leq F_{upper} \\ 0 & \text{otherwise} \end{cases}$$

Here, $S'(t, f)$ is the filtered spectrogram, the F_{lower} and F_{upper} are lower and upper cutoff

²<https://www.ecosounds.org/>

frequency and calculated as

$$\begin{aligned} F_{upper} &= F_{peak} + \beta \\ F_{lower} &= F_{peak} - \beta \end{aligned} \quad (4.1)$$

where F_{peak} is the peak frequency (Table 4.2), β is a threshold for determining the frequency bandwidth and set at 300 Hz based on the *reference data set*.

After bandpass filtering, noise reduction is essential for improving the segmentation result for the low signal to noise ratio in JCU recordings. Here, we use the method of Towsey et al. [2012] for noise reduction. Finally, we use the Härmä's method to detect individual syllables (Figure 4.3).

For the JCU recordings, eight frog species were used for the experiment. After syllable segmentation of continuous recordings, for each frog species, we randomly selected 30 syllables from segmentation results for subsequent analysis.

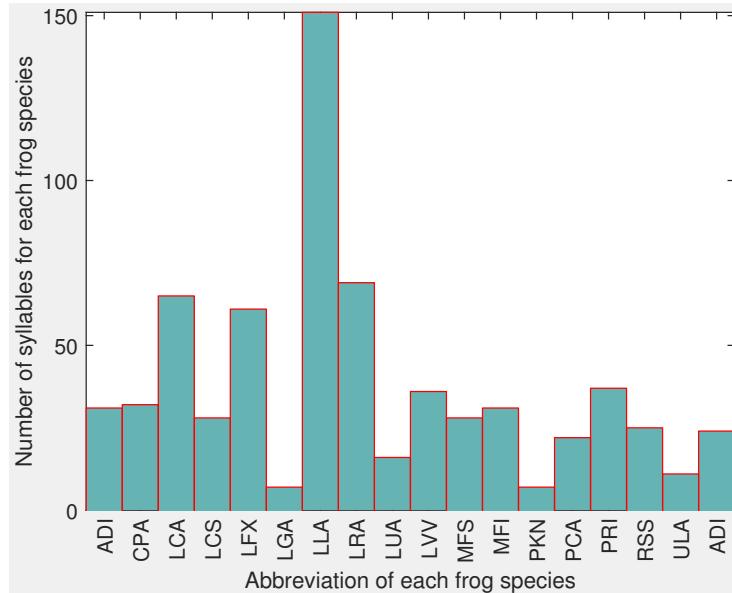

Figure 4.2: Distribution of syllable number for all frog species. The x-axis is the abbreviation of each frog species, and the corresponding scientific name can be found in Table 4.1.

4.2.4 Spectral peak track extraction

Spectral peak tracks (SPT) (also called frequency tracks) have been explored for studying birds [Heller and Pinezich, 2008, Jancovic and Kokuer, 2015] and whales [Roch et al., 2011]. In this chapter, the spectral peak track is used to represent the trace of a frog advertisement call, because frogs that are genetically related share more similar advertisement calls than distantly

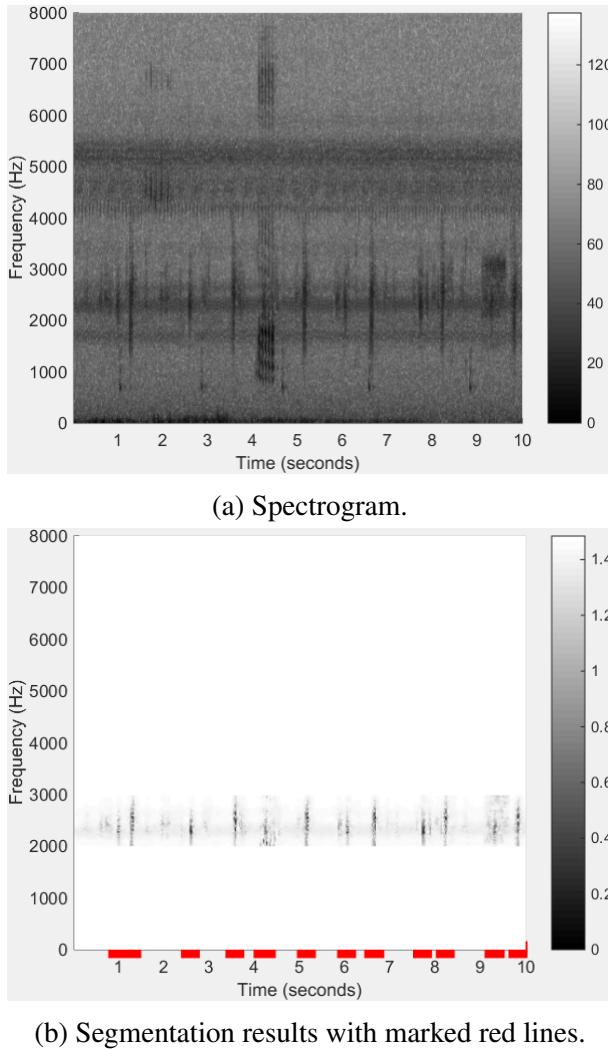

Figure 4.3: Segmentation results for *Uperolela mimula* using bandpass filtering, noise reduction and Härmä's method. The red line in (b) indicates the start and stop location of each segmented syllable.

related frogs [Gingras and Fitch, 2013]. The reasons for using SPT are (1) to isolate the desired frog calls from the background noise; (2) to extract corresponding SPT features. Here, the SPT method is reported in [Xie et al., 2015b].

For the SPT extraction algorithm, seven parameters need to be set (Table 4.3). The process for determining those parameters is explained in Section 3.

Before applying the SPT extraction algorithm, each syllable is transformed to a spectrogram with the following parameter settings (Hamming window, frame size is 128 samples, and window overlap is 90%). For the generated spectrogram, the maximum intensity (real peak) is selected from each frame with a minimum required intensity, I . Then, the time and frequency domain intervals between two successive peaks are calculated. If the time and frequency

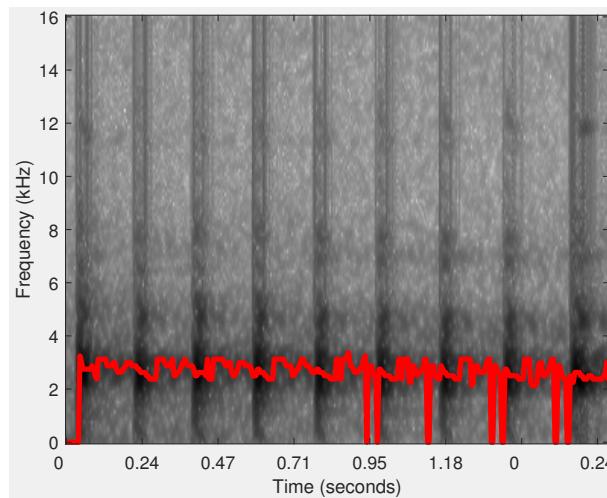

Table 4.3: Parameters used for spectral peak extraction

Parameter	Description
I (dB)	Minimum intensity threshold for peak selection
T_c (s)	Maximum time domain interval for peak connection
T_s (s)	Minimum time interval for stopping growing tracks
f_c (Hz)	Maximum frequency domain interval for peak connection
d_{min} (s)	Minimum track duration
d_{max} (s)	Maximum track duration
β (0~1)	Minimum density value

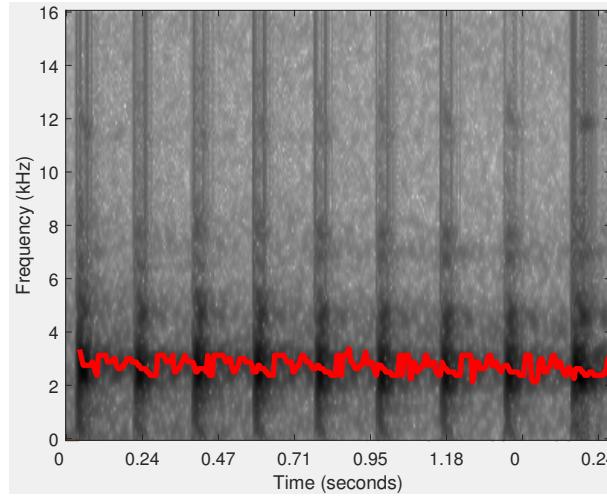

intervals are smaller than T_c and f_c respectively, one initial track (SPT_1) will be generated. After that, linear regression is applied to the generated track for calculating the position of the next predicted peak. Based on peaks $p_1(t_1, f_1)$ and $p_2(t_2, f_2)$ within the initial track (SPT_1), a and b in Equation (4.2) can be solved.

$$f = at + b \quad (4.2)$$

Based on a and b , the predicted peak \hat{p}_n of the following frame t_n can be calculated. Next, the time and frequency domain intervals between predicted peak (\hat{p}_n) and the real peak of the successive frame are recalculated. If the time and frequency intervals are smaller than T_c and f_c respectively, the real peak will be added to the initial track. After each peak is added to the initial track, linear regression is repeated to recalculate the next predicted peak using at most the last 10 included peaks. This iterative process continues until T_s is no longer satisfied. When no more peaks will be added to one track, the next step is to compare the duration and density of the track with d_{min} , d_{max} , and β . If all conditions are satisfied, then the track will be saved to the track list. The SPT results for *Neobatrachus sudelli* are shown in Figure 4.4. During the process of track extraction, time domain gaps are generated where the intensity threshold I is not reached. These gaps can be filled by predicting the correct frequency bin using linear regression, as illustrated in Figure 4.4.

(a) selected peaks below the intensity threshold I are set to zero.

(b) spectral peak track with predicted peaks using linear regression.

Figure 4.4: Spectral peak track extraction results for *Neobatrachus sudelli*. By filling the gaps within the track, the dominant frequency can be more accurately calculated.

4.2.5 Syllable SPT features

After SPT extraction, each SPT is expressed in the following format: (1) track start time t_s ; (2) track stop time t_e ; (3) frequency bin index for each of the peaks within the track f_t ($t_s \leq t \leq t_e$). Then, syllable features including track duration, dominant frequency, and oscillation rate are calculated based on the SPT.

- a) Track duration (second): Track duration (D_t) is directly obtained from the bounds of the track.

$$D_t = (t_e - t_s) * r_x \quad (4.3)$$

where r_x is the time domain resolution in unit second per frame.

b) Dominant frequency (Hz): Dominant frequency (\bar{f}) is calculated by averaging the frequency of all peaks within one track

$$\bar{f} = \sum_{t=t_s}^{t_e} f_t / (t_e - t_s + 1) * r_y \quad (4.4)$$

where r_y is the frequency domain resolution with unit frequency per bin, f_t is the frequency bin index of peak t .

c) Oscillation rate (Hz): Oscillation rate (O_r) represents the number of pulses per second. The algorithm for extracting oscillation rate is introduced and summarised as follows. First, the frequency domain boundary is defined based on the dominant frequency, and the power within the boundary is calculated. Then, the power vector is normalised, and the first and last 20% part of the vector is discarded, because of the uncertainty in the start and end of the syllables. Next, the autocorrelation with the length of the vector is calculated. Furthermore, a discrete cosine transform (DCT) is applied to the vector after subtracting the mean, and the position of the highest frequency (P_f) is achieved. Finally, the oscillation rate is defined as

$$O_r = \frac{P_f}{L_{dct}} * r_x * \gamma \quad (4.5)$$

where P_f is the position of the highest frequency values of the DCT result, L_{dct} is the length for applying DCT to the power vector set as 0.2 second in this experiment.

4.2.6 Wavelet packet decomposition

Wavelet packet decomposition (WPD) is a powerful tool for the analysis of non-stationary signals, which includes multiple bases and different basis [Selin et al., 2007]. With WPD, an original acoustic signal can be split into two frequency bands such as lower and higher frequency band. Then, both lower and higher frequency bands can be further continuously decomposed into two sub-bands, which produce a complete wavelet packet tree [Farooq and Datta, 2001]. Due to its ability for analysing a non-stationary signal, WPD has been used to analyse acoustic signals [Ren et al., 2008, Selin et al., 2007]. Here, WPD is used to obtain features for frog call classification.

4.2.7 WPD based on an adaptive frequency scale

To obtain robust features for frog call classification, the frequency scale used for WPD is crucial. In prior work [Biswas et al., 2014, Litvin and Cohen, 2011, Zhang and Li, 2015], different frequency scales have already been proposed for WPD. Bark-scaled WPD was proposed by Litvin and Cohen to separate blind source from a single channel audio source [Litvin and Cohen, 2011]. Biswas et al. [2014] used features based on ERB-scaled (Equivalent rectangular bandwidth) WPD for Hindi consonant recognition. Zhang and Li [2015] developed a method based on Mel-scaled WPD for bird sound detection with the SVMs classifier. However, most frequency scales used for WPD are developed for studying speech rather than frogs. Therefore, finding a suitable frequency scale for frogs to perform the WPD is important for obtaining features with strong discriminatory power. In this chapter, an adaptive frequency scale for WPD for frog calls is proposed, based on the dominant frequency of frog species to be classified. Specifically, the k-means clustering algorithm is used to cluster the dominant frequency of all syllables. Then, the centroids of the clustering result are used to generate the frequency scale. Here, the value of k for the k-means clustering algorithm is the same as the number of frog species to be classified, the distance function used is *city block* [Melter, 1987].

Based on the obtained frequency scale, an adaptive frequency scaled WPD method is proposed, which is described in Algorithm 1. The wavelet packet tree used for classifying 18 frog species is shown in Figure 4.5.

4.2.8 Feature extraction based on adaptive frequency scaled WPD

In previous studies [Bedoya et al., 2014, Xie et al., 2015b], MFCCs have been used for studying bioacoustic data, and it is used as the baseline for feature comparison in this chapter. Besides MFCCs, another feature set called Mel-scaled wavelet packet decomposition sub-band cepstral coefficients (MWSCCs) is also included in the comparison experiment [Zhang and Li, 2015], because it shows better performance than MFCCs for bird detection in a complex environment. In this chapter, we propose a novel feature set named *adaptive frequency scale wavelet packet decomposition sub-band cepstral coefficients* (AWSCCs) for frog call classification. The extraction procedure of AWSCCs is similar to MWSCCs. However, the frequency scale used for our AWSCCs is based on an adaptive frequency scale rather than the Mel-scale for MWSCCs. Meanwhile, after performing DCT, temporal feature integration is used for calculating the

Algorithm 1: Adaptive frequency scale for WPD

Data: $c_i (i = 1, 2, \dots, K)$, f_s , where K is the number of frog species to be classified, c_i is the centroid of the clustering results, $f_s = S_r/2$ where S_r is the sample rate of the audio recordings, which is 16 kHz here.

Result: Adaptive wavelet packet tree

begin

Step 1: Sort the centroid $c_i (i = 1, 2, \dots, K)$, and calculate the difference between the consecutive vectors of c , sort the difference and save it as $d_j (j = 1, 2, \dots, K - 1)$

Step 2: Calculate the decomposition level L based on the following rule

$$f_s/\min(d) \leq 2^{L-1}$$

where L is the minimum integer that satisfies that equation.

Step 3: Perform the wavelet packet decomposition

for $l = 1 : L$ **do**

1. Calculate the frequency resolution of level 1

for $i = 1 : K$ **do**

1: Put the c_i into the right frequency band

2: Count the number of c_i in each band (n)

if $n \geq 2$ **then**

| perform further decomposition to that particular node

else

| stop decomposition

statistics of feature vectors which generates different statistical types of AWSCCs. (see in Figure 4.6).

After syllable segmentation, the signal of one syllable is represented as $y(n)$, $n = 1, \dots, N$, where N is the length of one syllable of frog calls. Based on the $y(n)$, steps for AWSCCs extraction are described as follows:

1). Add Hamming window to the signal $y(n)$.

$$x(n) = w(n)y(n) \quad (4.6)$$

where $w(L)$ is the Hamming window function and defined as $w(n) = 0.54 - 0.46\cos(\frac{2n\pi}{L-1})$, L is the length of Hamming window and set as 128 samples here.

2). Perform wavelet packet decomposition spaced in adaptive frequency scale as described in Section 4.2.7.

$$WP(i, j) = \sum_{i=1}^M x(n)\psi_{(a,b)}(n) \quad (4.7)$$

where $WP(i, j)$ is the wavelet coefficients of the decomposition, i is the sub-band index, j is the index of wavelet coefficients, $\psi_{(a,b)}(n)$ is the wavelet base function, and we use 'Db 4'

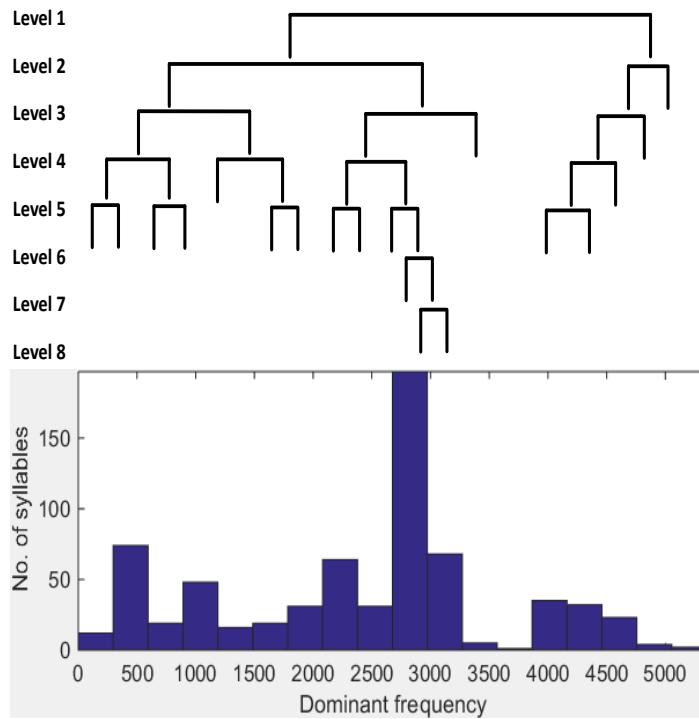

Figure 4.5: Adaptive wavelet packet tree for classifying twenty frog species. The upper image is the wavelet packet tree; the lower image is the histogram of dominant frequency for twenty frog species.

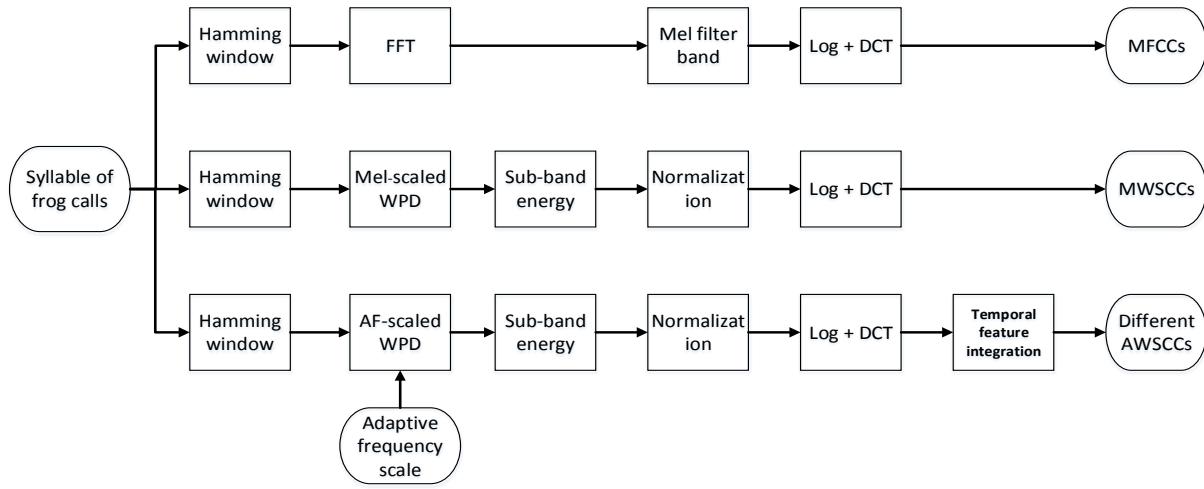

Figure 4.6: Description of three feature extraction methods including MFCCs, MWSCCs, and different statistical types of AWSCCs.

experimentally. Here, a and b are the scale and shift parameters, respectively. 'Db 4' represents the Daubechies wavelet transform which has four scaling and wavelet function coefficients.

3). Calculate the total energy of each sub-band.

$$WP_i = \sum_{j=1}^{M_i} [WP(i, j)]^2 \quad (4.8)$$

where $i = 1, 2, \dots, T$, and T is the total number of sub-band, and $j = 1, 2, \dots, M_i$, M_i is the total number of wavelet coefficients.

4). Normalise the energy of each sub-band.

$$SE_i = \frac{WP_i}{M_i} \quad (4.9)$$

where $i = 1, 2, \dots, T$.

5). Perform DCT on the logarithm sub-band energy for dimension reduction and obtain the feature AWSCCs.

$$AWSCCs(d) = \sum_{i=1}^T \log SE_i \cos\left(\frac{d(i - 0.5)}{T}\pi\right) \quad (4.10)$$

where $d = 1, 2, \dots, d'$, $1 \leq d' \leq T$, here d' is the dimension of AWSCCs, and set as 12 here. To keep the feature dimension consistency, the dimensions for MFCCs and MWSCCs are also set as 12 in this chapter, and the detailed steps for extraction can be found in [Bedoya et al., 2014] and [Zhang and Li, 2015].

6). Temporal feature integration

Here, the statistics of all feature vectors over each windowed signal are calculated, which include sum, average, standard deviation, and skewness. With randomly selected five instances for each frog species, the classification accuracy of averaged AWSCCs is higher than other statistics of AWSCCs. Therefore, only averaged AWSCCs are used in the subsequent experiment. To capture the dynamic information of the frog calls, the delta-AWSCCs are also calculated based on the averaged AWSCCs.

4.2.9 Classification

In this chapter, the k-nearest neighbour (kNN) and support vector machine (SVM) classification algorithms are used for frog call classification. The input parameters for each classifier are syllable features (SFs), MFCCs, MWSCCs, and different AWSCCs, and the output is the frog species. The descriptions of those two classifiers can be found in Chapter 3.2.5.

4.3 Experiment result and discussion

Several experiments are described for evaluating our proposed frog call classification system. First, the parameter tuning is discussed based on the reference data set. Then, the comparisons between all proposed features are studied. Finally, the classification results under different SNR are described.

4.3.1 Parameter tuning

There are five modules that require parameter tuning: syllable segmentation, spectral peak track, feature extraction, and classification (Figure 5.1).

For syllable segmentation, the window size and overlap are 512 samples and 25%, but the intensity thresholds are 10 dB and 5 dB for the commercial recordings and the JCU recordings, respectively.

In the spectral peak track determination, there are seven parameters (see in Table 4.3). The parameter settings are shown in Table 4.4.

Table 4.4: Parameter setting for calculating spectral peak track.

Parameter	Commercial recordings	JCU recordings
I (dB)	3	3
T_c (s)	0.005	0.1
T_s (s)	0.05	0.2
f_c (Hz)	800	800
d_{min} (s)	0.01	0.05
d_{max} (s)	2	2
β (0~1)	0.8	0.6

With a random parameter setting start, an iterative loop is performed for a fixed range of each parameter as seen in Table 4.1 to optimise those parameters.

For feature extraction, the window size and overlap are the same for MFCCs, MWSCCs, and AWSCCs using Hamming window, which are 128 samples and 90%, respectively. The dimensions of MFCCs, MWSCCs and AWSCCs are 12. For SFs and delta-AWSCCs, the dimensions are 3 and 24, respectively.

Following prior work [Han et al., 2011, Huang et al., 2009, Xie et al., 2015b], the distance function used for kNN is the Euclidean distance, and k is set as 3. As for the SVM classifier, the Gaussian kernel is used. Parameters α and v are selected independently for each feature set by grid-search using cross validation [Hsu et al., 2003].

4.3.2 Feature evaluation

All experiments are carried out in Matlab R2014b. Performance statistics are estimated with ten-fold cross validation. Totally, five feature sets including SFs, MFCCs, MWSCCs, and averaged AWSCCs, and delta-AWSCCs, are fed to two classifiers, which are the kNN and SVM classifiers. Due to the non-uniform distribution of the number of syllables for different frog species in the commercial recordings, a weighted classification accuracy is defined as

$$\text{weighted Acc} = \sum_{i=1}^N \text{Acc}(i) * \frac{n_i}{N} \quad (4.11)$$

where n_i is the number of syllables for frog species i , N is the number of syllables for all frog species, Acc is the classification accuracy for that particular frog species.

4.3.3 Comparison between different feature sets

The classification accuracy comparison for 18 frog species using five feature sets and two classifiers is shown in Table 4.5.

Table 4.5: Weighted classification accuracy (mean and standard deviation) comparison for five feature sets with two classifiers.

Feature set	Classification accuracy (%)	
	kNN	SVM
SFs	82.2 ± 11.2	84.2 ± 10.5
MFCCs	90.8 ± 8.6	92.8 ± 11.0
MWSCCs	95.0 ± 7.7	97.6 ± 5.7
Averaged AWSCCs	98.8 ± 4.2	99.0 ± 3.6
Delta-AWSCCs	99.2 ± 2.1	99.6 ± 1.8

In this experiment, the best classification accuracy is 99.6%, which is achieved by the delta-AWSCCs with the SVM classifier. Compared with the average AWSCCs, the delta-AWSCCs

achieved a slightly better performance. One may conjecture that the delta-AWSCCs can capture the dynamic information of the frog calls. For MWSCCs, the averaged classification accuracy of both classifiers is about 2% lower than that of averaged AWSCCs and delta-AWSCCs with 96.3%. The improvement shows that the proposed adaptive frequency scale can capture more information about frog calls than the Mel-scale (Figure 4.7).

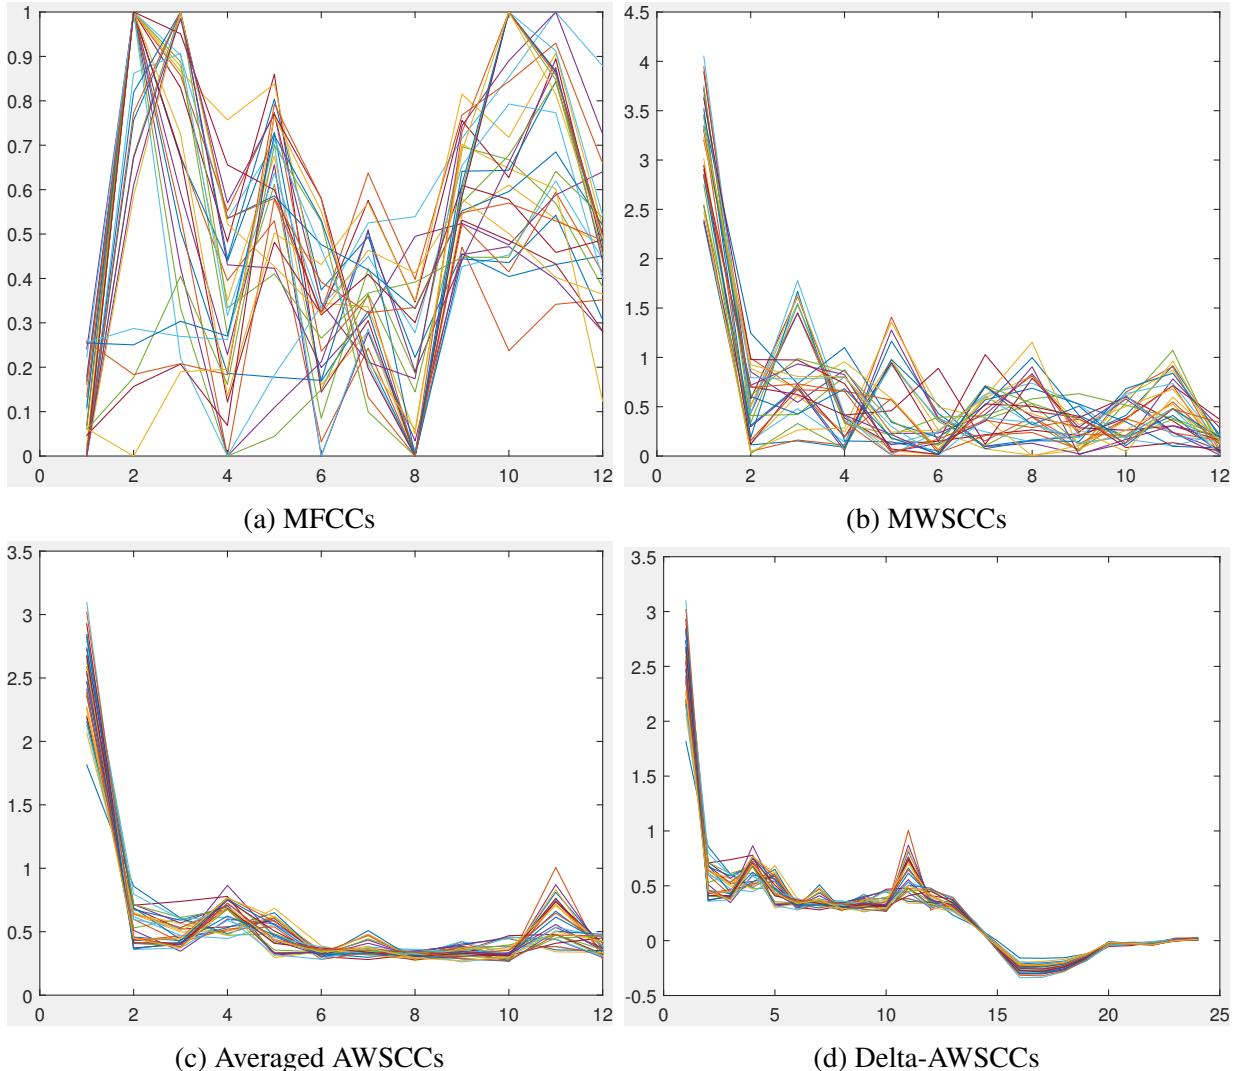

Figure 4.7: The feature vectors for 31 syllables of the single species, *Assa darlingtoni*. The x-axis is the feature index and y-axis is the feature value. Note that the feature vectors for averaged AWSCCs (c) and delta-AWSCCs (d) are more highly correlated than for the other two methods (a) and (b).

As for SFs and MFCCs, the averaged classification accuracy is much lower than AWSCCs, which is 83.2% and 91.8%, respectively. To explore the reason for the improvement of the proposed feature, the frog call classification accuracy of all frog species is shown in Table 4.6. However, only the features that use the SVM classifier are shown, because averaged accuracy of the kNN classifier (93.2%) is lower than the SVM classifier (94.64%).

Table 4.6: Classification accuracy of five features for the classification of twenty-four frog species using the SVM classifier. Here, Avg AWSCCs means the averaged AWSCCs.

Code	Classification accuracy (%)				
	SFs	MFCCs	MelCCs	Avg AWSCCs	Delta-AWSCCs

Table 4.6 lists the classification accuracy of all 18 frog species with five features. It can be seen from the table that delta-AWSCCs have an accuracy greater than 95% for all frog species. Compared with averaged AWSCCs, the classification accuracy of *Pseudophryne coriacea* (PCA) and *Litoria verreauxii verreauxii* (LVV) are improved to 100%; it might be that the delta-AWSCCs include the dynamic information of frog calls. For *Litoria revelata* (LRA), both the classification accuracy of averaged AWSCCs and delta-AWSCCs are lower than 100%; this is because the dominant frequency is quite similar with multiple frog species including *Assa darlingtoni* (ADI), *Litoria nasuta* (LNA) and *Litoria verreauxii verreauxii* (LVV). However, the classification of *Litoria revelata* (LRA) is 100% using Mel-scale based techniques, because the Mel-scale has a better frequency resolution for *Litoria chloris* (LCS) within its dominant frequency range. In Table 4.8, the classification accuracy of SFs and MFCCs is lower than the other three features, at only 84.2% and 92.8%, respectively.

The statistical significance of the results is shown in Table 4.7. The classification accuracy of average AWSCCs is not significantly lower than the delta-AWSCCs. However, the classification accuracy of MWSCCs, MFCCs and SFs is significantly lower than delta-AWSCCs.

Table 4.7: Paired statistical analysis of the results in Table 4.6. For the classification accuracy of each frog species, the paired Student t-test was conducted [Tanton, 2005].

Pairs	t-test results
Delta-AWSCCs - Avg AWSCCs	t=1.95 (not significant)
Delta-AWSCCs - MWSCCs	t=3.41 (significant at $p < 0.01$, df = 17)
Delta-AWSCCs - MFCCs	t=2.91 (significant at $p < 0.01$, df = 17)
Delta-AWSCCs - SFs	t=5.52 (significant at $p < 0.001$, df = 17)

Since our wavelet packet tree for feature extraction is obtained based on the frog species to be classified, two more experiments are used for further evaluation. The first experiment is to classify first ten frog species (No.1-10); the second is to classify the first fourteen frog species (No.1-14) (see Table 4.1). The wavelet packet tree for classifying ten and fourteen frog species is shown in Figure 4.8, which is different from the tree for classifying eighteen frog species. However, the Mel-scaled wavelet packet tree is the same for all experiments (see Figure 4.9). The classification results are shown in Table 4.8. Since the classification accuracy with averaged AWSCCs is very high for classifying ten and fourteen frog species, the delta-AWSCCs is not included in this experiment. Table 4.8 shows that averaged AWSCCs can achieve the highest classification accuracy for classifying different numbers of frog species. Since the averaged AWSCCs is adaptively extracted based on the data, more frog species do not cause a large decrease in the classification accuracy.

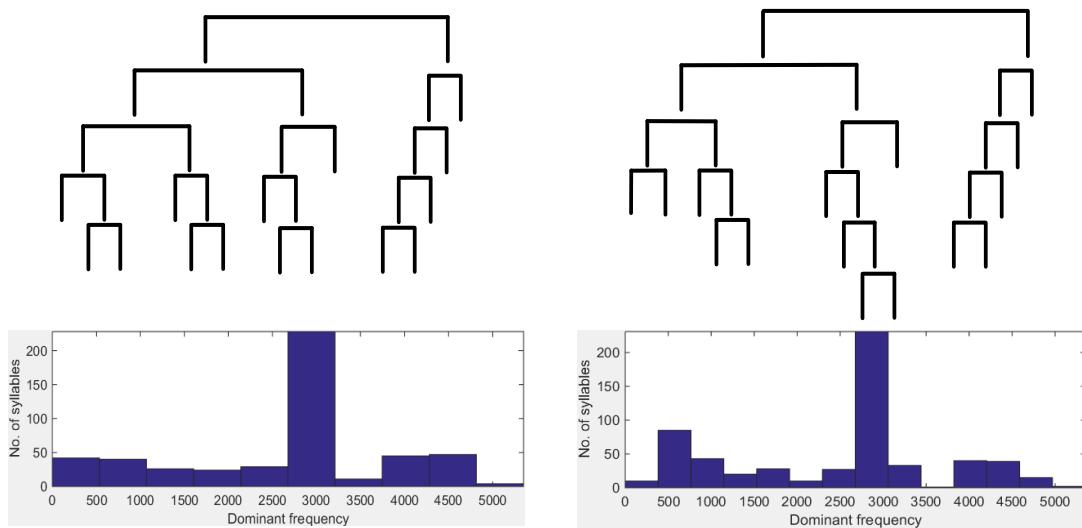

Figure 4.8: Wavelet packet tree based on adaptive frequency scale for classifying ten and fifteen frog species.

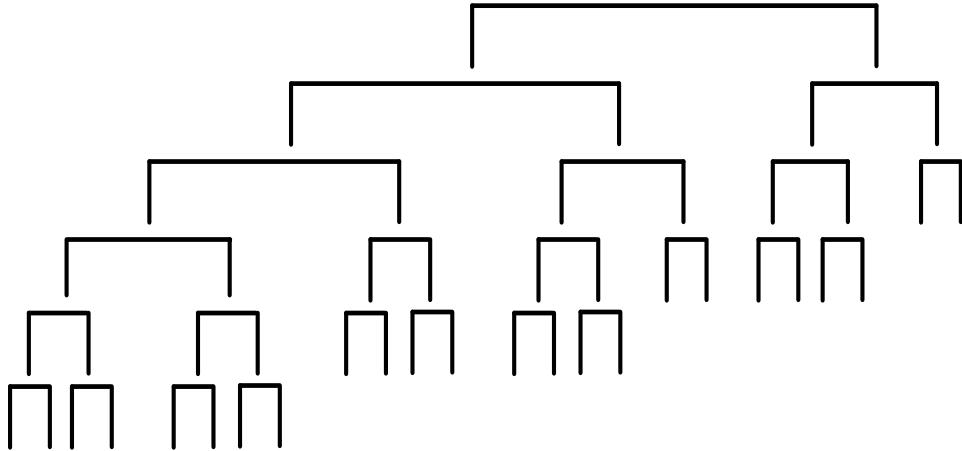

Figure 4.9: Mel-scaled wavelet packet tree for frog call classification.

Table 4.8: Classification accuracy (%) for classifying different number of frog species with four feature sets.

Features	SFs	MFCCs	MWSCCs	Averaged AWSCCs
18 frog species	84.2 ± 10.5	92.8 ± 11.0	97.6 ± 5.7	99.0 ± 3.6
14 frog species	89.6 ± 9.7	94.4 ± 8.5	99.2 ± 2.6	100.0 ± 0.0
10 frog species	94.6 ± 8.7	95.8 ± 8.6	100.0 ± 0.0	100.0 ± 0.0

4.3.4 Comparison under different SNRs

To further evaluate the robustness of the proposed feature, a Gaussian noise signal, with SNR of 40 dB, 30 dB, 20 dB, and 10 dB, is added to the original signal. The noise is added after syllable segmentation, because this chapter focuses on the development of novel features for classification rather than the segmentation method. The classification accuracy with five features under different SNRs is shown in Figure 4.10. Compared with MFCCs and MWSCCs, SFs has a stronger anti-noise performance, because the dominant frequency of SFs has a small variation under low SNR. Correspondingly, the adaptive frequency scale also has a small variation, because it is generated by means of applying the k-means clustering algorithm to the dominant frequency. Therefore, our proposed feature has a stronger anti-noise performance than other cepstral features (MFCCs and MWSCCs).

4.3.5 Feature evaluation using the real world recordings

Table 4.9 shows the classification accuracy comparison using our proposed feature to classify eight frog species obtained from the JCU recordings. Since calls of some frog species in the

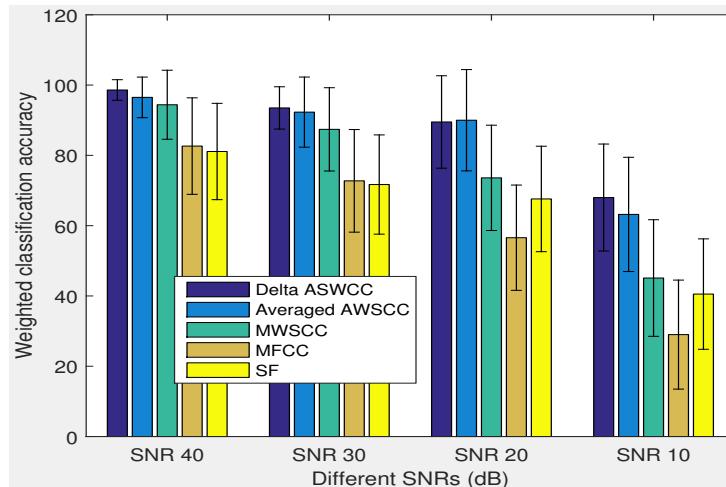

Figure 4.10: Sensitivity of five features for different levels of noise contamination.

JCU recordings do not have oscillation structure, SFs are not included for the comparison. Compared with other referred features, our proposed feature also achieves the best classification performance. Since the JCU recordings often have multiple calls from different frog species, spectral peak track occasionally can not capture the specific frog species (labelled species for that syllable), but other frog species to be classified; however, applying k-mean clustering to the dominant frequency calculated from the spectral peak track can reduce this deviation. Therefore, the frequency scale used for the WPD can be accurately achieved, which still leads to a high classification accuracy with the proposed feature.

Table 4.9: Classification accuracy using the JCU recordings.

Feature set	Classification accuracy (%)	
	kNN	SVM
MFCCs	67.5 ± 13.2	70.8 ± 14.1
MWSCCs	90.4 ± 9.2	91.6 ± 8.7
Averaged AWSCCs	94.1 ± 6.3	94.5 ± 5.8
Delta-AWSCCs	97.0 ± 5.2	97.4 ± 5.4

4.4 Summary and limitations

In this chapter, a novel feature extraction method for frog call classification is developed using the adaptive frequency scaled wavelet packet decomposition. With segmented syllables, spectral peak track is first extracted from each syllable. Then, track duration, dominant frequency, and oscillation rate are calculated based on each track. Next, a k-means clustering algorithm

is applied to the dominant frequency, which generates the frequency scale for WPD. Finally, a new feature set, AWSCCs, is calculated. Since the feature extraction method is developed based on the data itself, the wavelet packet tree varies according to the frog species to be classified. Compared with the Mel-scaled WPD tree, the proposed adaptive wavelet packet tree can better fit the dominant frequency distribution of the frog species to be classified. With the proposed frequency scale, the call characteristics of those frog species to be classified can be enhanced, while the background noise and calls from other animals will be suppressed. Therefore, the proposed feature sets can achieve a higher accuracy for the classification of frog calls than others. Meanwhile, since the frequency scale is calculated based on the dominant frequency of those frog species to be classified, our proposed wavelet tree structure is more accurate and efficient in classifying the frog calls when compared with Mel-scale (Figure 4.8 and Figure 4.9).

The feature extraction algorithm is designed for classifying frog calls. For frog calls, the typical structure in a spectrogram is frequency contour (named spectral peak track in this chapter) which is within a given frequency range starting at a given time [Mellinger et al., 2011]. For other organisms that have similar frequency contour structures such as the whistles of dolphins, and chirps of birds [Chen and Maher, 2006], spectral peak tracks can also be extracted from the spectrograms of their calls. Based on those spectral peak tracks, dominant frequency can be calculated. For the subsequent analysis, the features can be calculated using the same process as described in this chapter. For those organisms without clear frequency contour structure, this proposed method can also be used by enhancing the frequency contour structure, which can be realised by applying a small window size and a large window overlap to the recording waveform.

The oscillation rate is calculated based on the spectrogram, which is generated by applying STFT to the waveform. However, when the temporal gap is smaller than the window size used for STFT, the oscillation structure will disappear. Therefore, finding new techniques for translating the 1-D signal to 2-D signal is our future direction. Since the frequency scale is generated based on the dominant frequency, this technique can be applied to other organisms that have clear frequency contour structure. Modifying this algorithm to those organisms without a clear frequency contour structure needs to be solved. This research also plans to include additional experiments that test a wider variety of audio data from different geographical and environment conditions. Other animal calls such as birds, insects, and whales can also be studied. Furthermore, the idea of developing new features based on the data itself will be

explored.

Chapter 5

Multiple-instance multiple-label learning for the classification of frog calls with acoustic event detection

5.1 Overview

This chapter presents a method for the classification of simultaneously vocalising frog species in low signal-to-noise ratio (SNR) recordings. In Chapters 3 and 4, frog call classification is solved using a SISL framework, which cannot reflect the nature of automatically collected environmental recordings. Most automatically collected field recordings have low SNR and consist of multiple simultaneous animal vocal activities including frogs, birds, crickets, and so on. This character of environmental acoustic recordings makes the MIML learning a suitable classification framework. To be specific, individual frog syllables in one audio clip are regarded as *multiple instance*, and the frog species included in that audio clip denote *multiple labels*. The key part of this MIML classification framework for studying frog calls is to detect individual syllables in environmental recordings with multiple simultaneously vocalising frog species. After syllable detection, standard acoustic features and MIML classifiers can be used to perform the MIML classification.

To evaluate our proposed MIML classification framework, a representative sample of 342 10-second recordings was exported from the database and split into training and testing sets. The performance is evaluated based on the MIML learning measures. A validation dataset of 10 10-second recordings for each frog species is constructed for parameter tuning. Experimental

results demonstrate that the MIML classification framework can be successfully adopted to classify multiple simultaneously vocalising frog species in low SNR recordings.

5.2 Materials and methods

Our frog call classification system consists of four steps: signal processing, acoustic event detection, feature extraction, and classification (Fig. 5.1). Detailed description of each step is listed in the following sections.

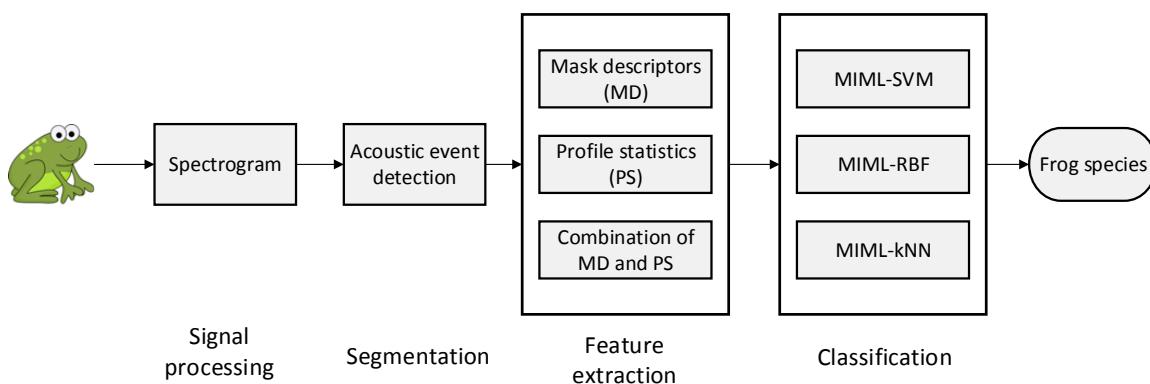

Figure 5.1: Flowchart of a frog call classification system using MIML learning

5.2.1 Materials

All recordings selected for this chapter were obtained from three sites in Queensland, Australia: *Kiyomi dam*, *Stony creek dam* and *BG creek dam*, using a battery-powered acoustic sensor (stored in a weather proof metal box) with an external microphone. The recordings were stored on 16 GB SD cards in 64 kbps MP3 mono format. All recordings were collected from February, 2014 to April, 2014, because it is the breeding season in Queensland when male frogs make calls to attract females for the purpose of reproducing. All recordings started around sunset, finished around sunrise every day and have a duration of 12 hours. In this chapter, a representative sample of 342 10-second recordings was selected to train and test our proposed algorithm for predicting which frog species are present in a 10-second recording. All the 10-second recordings were manually labelled by an ecologist with eight frog species. The acoustic parameters of eight frog species averaged for ten randomly selected syllables of each frog species are shown in table 5.1. It is worth noting that the parameters of table 5.1 are slightly different from table 4.2 with an acceptable variation.

Table 5.1: Dominant frequency (F_0) and syllable duration (T_s) of eight frog species averaged for ten randomly selected syllables.

Frog species	Code	Dominant frequency (Hz)	Syllable duration(ms)
<i>Canetoad</i>	CAD	560	NA
<i>Cyclorana novaehollandiae</i>	CNE	610	400
<i>Limnodynastes terraereginae</i>	LTE	610	100
<i>Litoria fallax</i>	LFX	4000	280
<i>Litoria nasuta</i>	LNA	2800	160
<i>Litoria rothii</i>	LRI	1800	500
<i>Litoria rubella</i>	LRA	2300	580
<i>Uperolela mimula</i>	UMA	2400	120

Each recording includes between one and five frog species. Following the prior work of [Briggs et al., 2012], we assume that recordings without frog vocalisations can be filtered out during the acoustic event detection process.

5.2.2 Signal processing

All the recordings were first re-sampled at 16 kHz. A spectrogram was then generated by applying short-time Fourier transform (STFT) to each recording. Specifically, each recording was divided into frames of 512 samples with 50% frame overlap. A fast Fourier transform was then performed on each frame with a Hamming window, which yielded amplitude values for 256 frequency bins, each spanning 31.25 Hz. The final decibel values (S) were generated as

$$S_{tf} = 20 * \log_{10}(A_{tf}) \quad (5.1)$$

where A denotes the amplitude value, $t = 0, \dots, T - 1$ and $f = 0, \dots, F - 1$ represent time and frequency index, T and F are 256 frequency bins and 625 frames, respectively.

5.2.3 Acoustic event detection for syllable segmentation

The aim of AED is to detect a specified acoustic event in audio data. In this chapter, we use AED for frog syllable segmentation. Since all the recordings are collected from the field, there are many overlapping vocal activities from different sources. Traditional methods for frog syllable segmentation are based on time domain information [Huang et al., 2009, Somervuo et al., 2004], which cannot address those recordings. Here, we modified the AED method developed by Towsey et al. [Towsey et al., 2012] for syllable segmentation. The detail of our AED method is

described as follows:

Step 1: Wiener filtering

A 2-dimensional Wiener filter is applied to the spectrogram image over a 5×5 time-frequency grid to reduce the background graininess, where the filter size is selected after the consideration of trade-off between removing the background graininess and blurring the acoustic events.

$$\hat{S}_{tf} = \mu + \frac{(\sigma^2 - \nu^2)}{\sigma^2} (S_{tf} - \nu) \quad (5.2)$$

where μ and σ^2 are local mean and variance, respectively; ν^2 is the noise variance estimated by averaging all local variances.

Step 2: Spectral subtraction

Wiener filtering can successfully remove the graininess, but some noises, such as wind, insect, motor engine that cover the whole recording can not be addressed using Wiener filtering. Here, a modified spectral subtraction method is employed to deal with those noises.

Algorithm 2: Spectral Subtraction

Data: \hat{S}_{tf} , spectrogram after Wiener filtering.

Result: $\hat{S}'_{tf} = \hat{S}_{tf}$, noise reduced spectrogram.

begin

Construct an array of the modal noise values for all frequency bins;

for $f \in F$ **do**

1. calculate the histogram of the intensity value over each frequency bin

2. smooth the histogram array with a moving average window of size 7

3. regard the modal noise intensity at the position of maximal bin in the left-side of the histogram

Smooth the array with a moving average filter with window of size 5;

for $f \in F$ **do**

1. subtract the modal noise intensity

2. truncated negative decibel values to zero

Step 3: Adaptive thresholding

After noise reduction, the next step is to convert a noise reduced spectrogram \hat{S}'_{tf} into the binary spectrogram S'_{tf}^b for the event detection. Here, an adaptive thresholding method named *Otsu thresholding* [Otsu, 1975] is employed to find an optimal threshold.

$$\phi_b^2(k) = w_1(k)w_2(k)[\mu_1(k) - \mu_2(k)]^2 \quad (5.3)$$

where $w_1(k) = \sum_0^k p(j)$ is calculated from the histogram as k , $p(j) = n(j)/N$ are the values of the normalised gray level histogram, $n(j)$ is the number of values in level j , N is the total number of values over the whole spectrogram image, $\mu_1(k) = [\sum_0^k p(j)x(j)]/w_1$, $x(j)$ is the value at the center of the j th histogram bin. Then, the threshold, T_0 , is calculated as

$$T_0 = (\phi_{b1}^2(k) + \phi_{b2}^2(k))/2 \quad (5.4)$$

Step 4: Events filtering using dominant frequency and event area

Since not all detected events correspond to frog vocalisations, to further remove those events that are not from the listed frog species in section 5.2.1, dominant frequency (F_0) and area of the event (Ar) are used for filtering.

Algorithm 3: Event filtering based on dominant frequency and event area

Data: S_{tf}^b , spectrogram; $t_s(n)$, $t_e(n)$, $f_l(n)$, $f_h(n)$, location of each acoustic event n ; $F_0(i)$, dominant frequency of frog species i .

Result: \tilde{S}_{tf} , spectrogram after events filtering.

begin

Calculate the area of each acoustic event n .

$Area(n) = (t_e(n) - t_s(n)) * (f_h(n) - f_l(n))$

for $n \in N_{e1}$ **do**

if $Ar(n) \geq Ar_l$ **then**

split event n into small events

where Ar_l is set as 3000 pixels.

Filter events using dominant frequency $f_d(n) = \sum_{t=t_s(n)}^{t_e(n)} F(t)/t_e(n) - t_s(n)$

where $F(t)$ is the peak frequency of each frame within the event area

for $n \in N_{e2}$ **do**

for $i \in I$ **do**

if $f_d(n) \geq F_0(i) + \theta$; $f_d(n) \leq F_0(i) - \theta$ **then**

$f_d(n) = 0$;

where θ is frequency range and set as 300 Hz.

Remove small acoustic events except frequency band between θ_l and θ_h

for $n \in N_{e2}$ **do**

if $Ar(n) \leq Ar_s$ **then**

remove event n

where Ar_s is set as 300 pixels, θ_l and θ_h are set as 300 Hz and 800 Hz, respectively.

Because the area of LTE is smaller than Ar_s .

Step 5: Region growing

A region growing algorithm is used to obtain the contour of the particular acoustic event [Mallawaarachchi et al., 2008]. To get the accurate boundary of each acoustic event and improve

the discrimination of extracted features, a 2-dimensional region growing algorithm is applied to obtain the accurate event shape within each segmented event. First, the point having the maximal intensity value within the event area is selected as the seed. Then, the neighbourhood pixels of the seed(s) above the threshold are located and assigned to the output image, and new added pixels are used as seeds for further processing. Finally, when all the pixels that satisfy the criteria are added to the output image, the recursive algorithm will stop and get the final results (Figure 5.3). Here, the threshold value is empirically set as 5 dB.

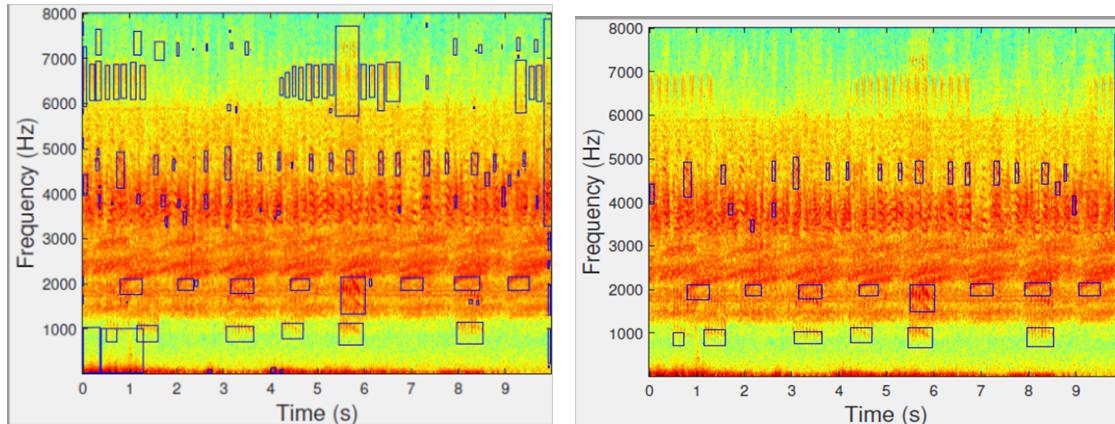

Figure 5.2: Acoustic event detection results before (Left) and after (Right) event filtering based on dominant frequency. Here, blue rectangle means the time and frequency boundary of each detected event.

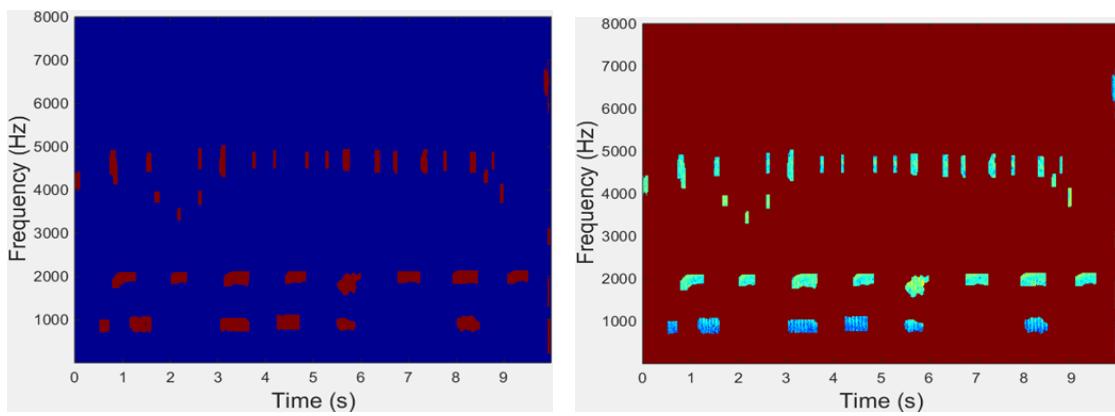

Figure 5.3: Acoustic event detection results after region growing. Left: binary segmentation results; Right: segmented frog syllables.

5.2.4 Feature extraction

Based on acoustic event detection results, two feature sets are first calculated to describe each event (syllable): mask descriptors and profile statistics [Briggs et al., 2012]. Here, we exclude *histogram of orientation (HOG)* from our feature set, because the previous studies have

already demonstrated its poor classification accuracy [Briggs et al., 2012, Ruiz-Munoz et al., 2015]. For mask descriptors, it is used to describe the syllable shape including minimum frequency, maximum frequency, bandwidth, duration, area, perimeter, non-compactness, rectangularity. For profile statistics, there are time-Gini, frequency-Gini, frequency-mean, frequency-variance, frequency-skewness, frequency-kurtosis, frequency-max, time-max, mask-mean, and mask standard deviation. A third feature set consists of all features.

5.2.5 Multiple-instance multiple-label classifiers

After feature extraction, three MIML learning algorithms are evaluated for the classification of multiple simultaneous vocalising frog species: MIML-SVM, MIML-RBF, and MIML-kNN. With the form of event-level distance measure, the MIML problem can be reduced to a single-instance multiple-label problem by associating each event with an event-level feature [Briggs et al., 2012]. Here, the maximal and average Hausdorff distances between two syllables are used by MIML-SVM and MIML-RBF, respectively. For MIML-kNN, the nearest neighbour is used to assign syllable-level features.

5.3 Experiment results

5.3.1 Parameter tuning

There are three modules, the parameters of which need to be discussed: signal processing, acoustic event detection, and classification. For signal processing, the window size and overlap are 512 samples and 50%, respectively. During the process of acoustic event detection, four thresholds for event filtering need to be determined, which are small and large area threshold, and frequency boundary for events filtering. All those thresholds were determined empirically by applying various combinations of thresholds to the constructed validation dataset. For MIML-SVM classifiers, the parameters used are (C, γ, r) and set as $(0.1, 0.6, 0.2)$ experimentally. For MIML-RBF, the parameters are (r, μ) and set as $(0.1, 0.6)$. For MIML-kNN, the number of references (k) and citers (k') are 10 and 20, respectively.

5.3.2 Classification

In this chapter, all the algorithms were programmed in Matlab 2014b. Each MIML algorithm is evaluated with five-fold cross-validation on the collection of 342 species-labelled recordings. Five evaluation rules are used for comparing the performance with the combination of three feature sets and three ML algorithms: Hamming loss, Rank loss, Average precision, One error, Exampled based F_1 , and Micro F_1 [Madjarov et al., 2012, Zhou et al., 2008]. The value range of all five evaluation rules is between 0 to 1. The definition of each evaluation rule is described as follows:

(1) Hamming loss is defined as the fraction of labels that are incorrectly predicted for an instance and the normalised Hamming loss which is normalised over instances is reported. This metric is defined as

$$hammingLoss = \frac{1}{N} \sum_{i=1}^N \frac{1}{Q} |h(x_i) \Delta y_i| \quad (5.5)$$

where Δ denotes the symmetric difference between two instances, N is the number of instances and Q is the total number of possible labels. y_i denotes the ground truth of instance x_i , and $h(x_i)$ denotes the predictions for the same instance.

(2) Ranking loss evaluates the average fraction of label pairs that are reversely ordered for the particular instance given by

$$rankingLoss = \frac{1}{N} \sum_{i=1}^N \frac{|D_i|}{|y_i||\bar{y}_i|} \quad (5.6)$$

where $D_i = (\lambda_m, \lambda_n) | f(x_i, \lambda_m) \leq f(x_i, \lambda_n), (\lambda_m, \lambda_n) \in y_i \times \hat{y}_i$, while \bar{y} denotes the complementary set of y in L , and $L = \lambda_1, \lambda_2, \lambda_3, \dots, \lambda_Q$, λ represents the label.

(3) One error evaluates how many times the top-ranked label is not in the set of relevant labels of the instance. This evaluation metric is defined as

$$oneError = \frac{1}{N} \sum_{i=1}^N [[argmax_{\lambda \in y} f(x_i, \lambda)] \notin y_i] \quad (5.7)$$

(4) Coverage evaluates how far, on average, we need to go down the list of ranked labels in

order to cover all the relevant labels of the example. The definition of this metric is shown as

$$\text{coverage}(f) = \frac{1}{N} \sum_{i=1}^N \maxrank_f(x_i, \lambda) - 1 \quad (5.8)$$

where $\text{rank}_f(x_i, \lambda)$ maps the outputs of $f(x_i, \lambda)$ for any $\lambda \in L$ to $\lambda_1, \lambda_2, \dots, \lambda_Q$, so that $f(x_i, \lambda_m) \leq f(x_i, \lambda_n)$ implies $\text{rank}_f(x_i, \lambda_m) \leq \text{rank}_f(x_i, \lambda_n)$

(5) Micro-AUC is defined as each point on the ROC curve corresponds to a pair (TPR, FPR) for one threshold. The area under this ROC curve is called Micro-AUC. Here, the definition of TPR and FPR can be found in Equation (2.3) and (2.6)

The values for Hamming loss, Rank loss, One-error, Coverage, and Micro-AUC range from 0 to 1. For Hamming loss, Rank loss, one-error and coverage, 0 denotes the perfect result, and 1 means the wrong prediction of all labels over every instance, whereas for micro-AUD, the values have the completely opposite meanings.

The $\frac{\text{positive}}{\text{negative}}$ is defined as $1 - \text{hammingLoss}$ and it is 0.818 for MIML-RBF with Mask descriptors (MD). MD and profile statistical (PS), and all features (AF) are put into the three classifiers, respectively. The accuracy measure for each MIML classifier is shown in Table 5.2. Here, the best classification accuracy is achieved using MIML-RBF with MD. For each classifier, the classification accuracy of MD is higher than PS and AF, which indicates that the event shape has a better discriminability than the event content. To give a concrete view of predictions, the results of five randomly selected recordings using MIML-RBF are shown in Table 5.3. From the table, we can see that recordings of No.1 and No.3 are accurately predicted.

Table 5.2: Accuracy measures for MIML classifiers with different feature sets. Here, \downarrow indicates that smaller values imply higher accuracy, while \uparrow has the completely opposite meanings.

Feature	Algorithm	Hamming loss \downarrow	Rank loss \downarrow	One-error \downarrow	Coverage \downarrow	Micro-AUC \uparrow

5.4 Discussion

Since most recordings used in this chapter contain multiple simultaneously vocalising frog species, the traditional single-instance single-label classification framework is no longer suitable. A novel framework for the classification of multiple simultaneous vocalising frog species in environmental recordings is proposed, which is adopted from [Briggs et al., 2012], a study on birds. Differently from that work, this research designs a new acoustic event detection method for syllable segmentation rather than using a supervised learning algorithm. It is because there are few annotated frog recordings. As for the classification results, our proposed framework can achieve an acceptable classification accuracy. All the features used in this study are calculated from the segmented syllables. The accuracy of the segmentation therefore directly affects the final classification performance.

5.5 Summary and limitations

In this chapter, we propose a novel framework for the classification of multiple simultaneous vocalising frog species in environmental recordings. To the best of our knowledge, this is the first study that focuses on the frog recordings using the MIML algorithm. Since multiple frog species tend to call simultaneously, the MIML algorithm is more suitable for dealing with those recordings than single-instance single-label classification. Individual frog syllables are first segmented using AED. Then, three feature sets, MD, PS, and AF, are calculated from those segmented syllables. Next, a bag generator is used to construct a feature set with extracted features from each syllables. Finally, three MIML classifiers are used for the classification of frog calls with the best true positive/negatives of 81.8%. Future work will focus on the study of novel features and MIML classifiers to further improve the classification performance. Current

classification results are highly affected by the syllable segmentation results, and the use of AED cannot accurately segment all the syllables. One solution is to prepare an annotated dataset and apply supervised learning algorithms for the segmentation task. Another is to use a different classification framework, which does not need the segmentation process, and we examine this option in the next chapter

Chapter 6

Estimating frog calling activity and species richness based on acoustic event detection and multi-label learning

6.1 Overview

This chapter describes the research conducted for estimating frog calling activity and species richness. Different from Chapter 5 that use AED for estimating frog species richness, AED is used to estimate the frog calling activity in this chapter. In Chapter 5, acoustic features are calculated based on the results of AED to estimate frog species richness, but the accuracy of AED results directly affect the MIML classification performance. To reduce the bias introduced by AED, this research presents global feature representations for the classification of recordings with multiple frog species. The feature representation is extracted from the whole recording without the syllable segmentation. Therefore, the classification process can be framed as a ML learning task.

Three global feature representations are calculated to classify each 10-second recording: LPCs, MFCCs, and PWSCCs. Both MFCCs and PWSCCs are similar to the features used in Chapter 4. The difference is that each 10-second recording is divided into three equal parts, and both MFCCs and PWSCCs are calculated from each part and combined as the final feature, which can obtain more temporal information.

Furthermore, this proposed classification framework is conducted for a long-term analysis. Both frog calling activity and species richness during the breeding season are estimated. Also,

the correlations between frog calling activity/species richness with weather variables are studied to reflect the relationship between them.

The architecture of this frog calling activity and species richness estimation system is shown in Figure 6.1. The system contains three parts: frog calling activity estimation, frog species richness estimation, and correlation analysis. Each part is discussed in detail in the following subsections.

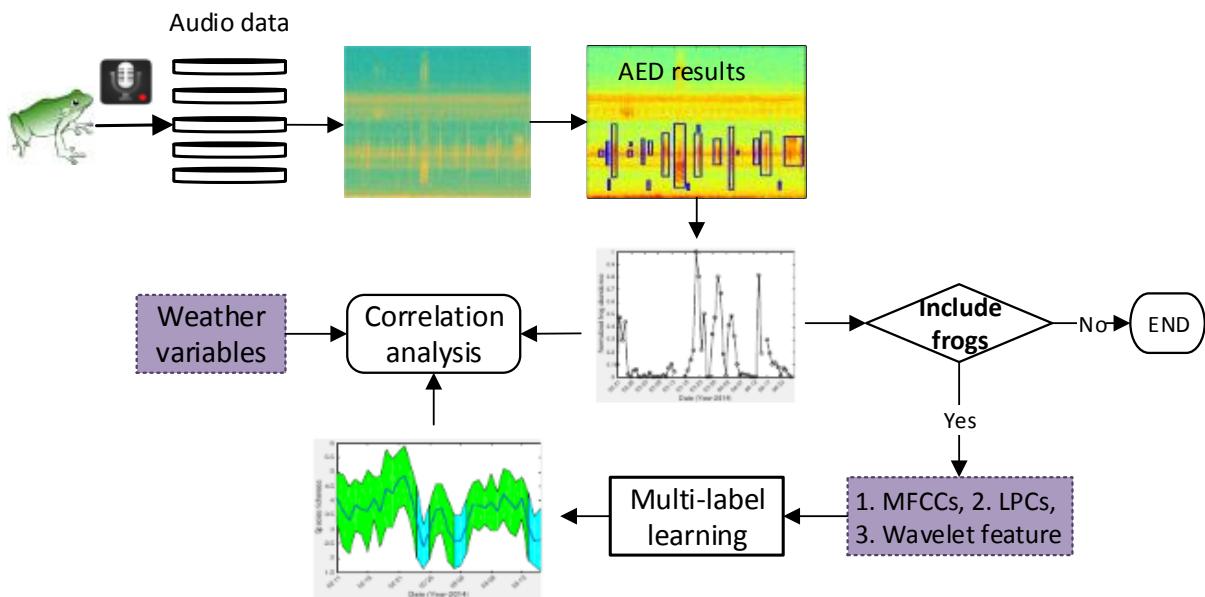

Figure 6.1: Flowchart of a frog call classification system using AED and ML learning

6.2 Acquisition of frog call recordings

To evaluate the proposed algorithm, the same dataset with Chapter 5 is used. The description of this dataset can be found in Chapter 5.2.1. Besides the representative dataset, this study sampled 10-second recordings every 10 minutes from continuous recordings over three months. Finally, there are 4170, 4908, and 1544 10-second recordings for *Kiyomi dam*, *Stony Creek dam* and *BG Creek dam*, respectively, which are used for long-term acoustic monitoring. Here, the number of recordings of these sites is different due to the data loss in some days.

We first manually inspect spectrograms of ten randomly selected call examples for each frog species. Two parameters, dominant frequency and syllable duration, are measured and averaged, as listed in Table 5.1, which are used as prior information for subsequent analysis.

6.3 Experiment setup

Each 10-second recording is divided into frames of 512 samples and 50% frame overlap for STFT. A_{large} and A_{small} , which are used for area filtering in AED, are empirically set at 3000 pixels and 300 pixels, respectively. Allowed fluctuations in both sides of dominant frequency are 300 Hz for dominant frequency filtering. For WP-based feature, window size and overlap are 512 samples and 50%, the window function is a Hamming window. All algorithms were programmed in Matlab 2014b except ML learning, which was implemented in Meka 1.7.7⁴.

6.4 Frog calling activity

6.4.1 Frog calling activity of each 10-second recording

Frog calling activity is estimated through the detection of acoustic events in a spectrogram image. Here, the spectrogram is generated by applying short-time Fourier transform (STFT) to each 10-second recording. The description of the AED method is shown in Chapter 5.2.3.

The frog calling activity of each 10-second recording is estimated as

$$F_{abun} = \sum_{n=1}^N \sum_{i=1}^I \sum_{j=1}^J A_{i,j}(n)^2 \quad (6.1)$$

Here, $A_{i,j}$ represents the decibel value of location (i, j) within each acoustic event n in the spectrogram, i is the temporal index, j is the frequency index, I and J are the height and width of each acoustic event.

6.4.2 Long-term monitoring of frog calling activity

Figure 6.3 shows the frog calling activity results of three selected sites over the whole frog breeding season. It can be found that the frog calling activity of the same site changes a great deal over time. In the *Kiyomi dam*, frog calling activity is relatively high from February 21 to February 25. However, frog calling activity is quite low in two periods, which are February 26 to March 11 and April 07 to April 12. The highest calling activity of this site is achieved on March 22. However, the highest calling activity for *Stony Creek dam* and *BG Creek dam*

⁴<http://meka.sourceforge.net/>

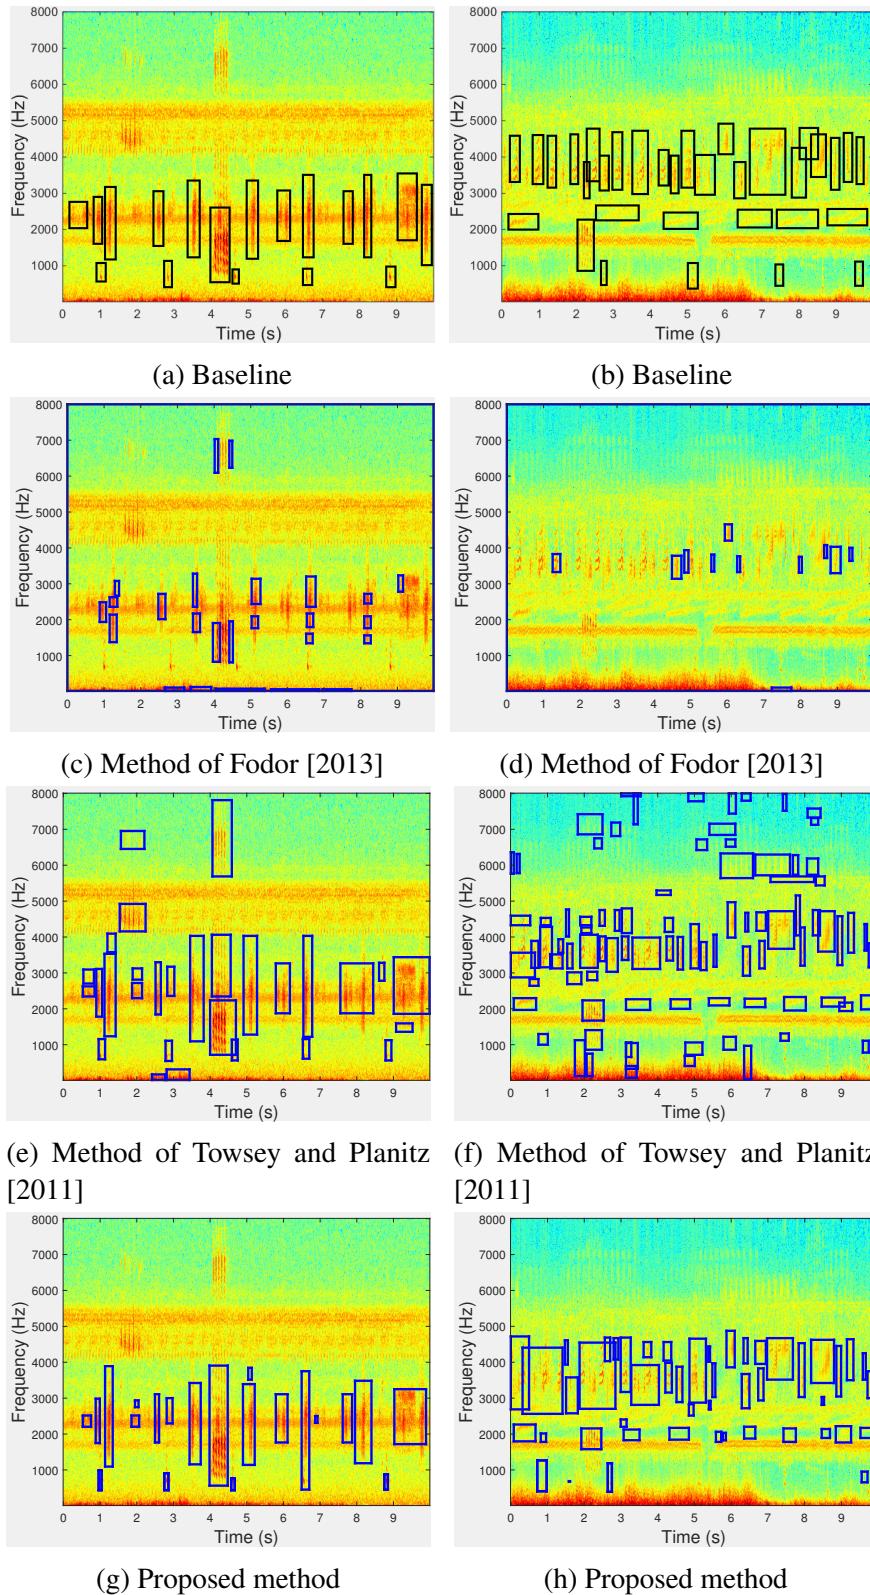

Figure 6.2: AED for frog calling activity estimation using different methods. For each row, different methods are applied to the same recordings. The baseline of the detection results is shown in the first row; detected frog calls are drawn using a blue rectangle. For each column, different methods are used for the same recording.

is obtained in February, which shows that frog calling activity of different sites often varies a lot for different environments. Recordings of 47 days of all three sites do not record frog calls. In the subsequent analysis, only those recordings with frog calls are used for frog species richness estimation.

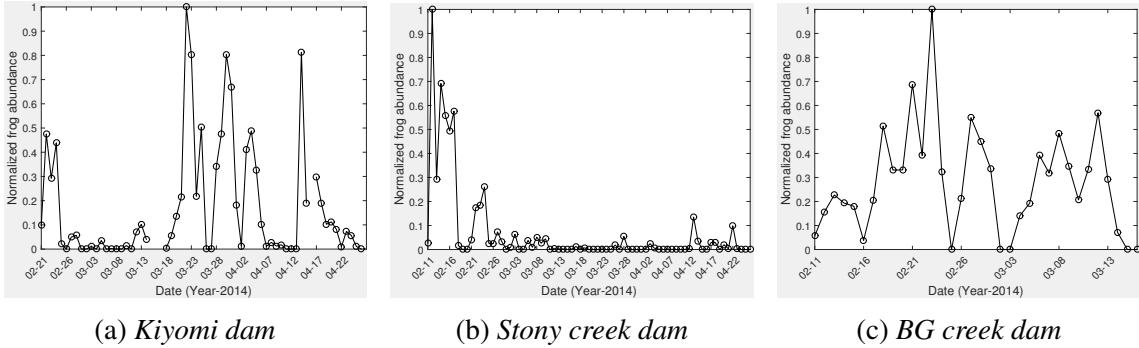

Figure 6.3: Frog calling activity estimation of different sites: *Kiyomi dam*, *Stony Creek dam* and *BG Creek dam*. For *Kiyomi dam*, three days do not record any acoustic data and then there is no value in those particular days. All the frog calling activity value is normalised to [0 1].

6.5 Frog species richness

Frog species richness is estimated by predicting the species presence/absence of each sampled recording. Since many sampled recordings consist of multiple frog species, one direct solution is to assign each recording with a set of labels (frog species) for explicitly expressing its semantics [Zhang and Zhou, 2014]. Therefore, ML learning is adopted to classify each sampled recording.

Extracting discriminating features, which maximise between-group (inter-specie) dissimilarity and minimise within-group (intra-specie) dissimilarity, is very important for achieving high classification performance [Bedoya et al., 2014, Huang et al., 2009]. In this chapter, feature extraction is performed based on WPD using a modified version of the method introduced in Chapter 4 and detailed below.

For feature extraction, constructing a suitable frequency scale for a WP tree based on the dominant frequency of each frog species is the first step, because different frog species tend to have different dominant frequencies [Gingras and Fitch, 2013]. In Chapter 4, k-means clustering was first applied to the extracted dominant frequencies of training data. Then, the frequency scale was built by sorting clustering centroids to construct the WP tree. In this

chapter, the prior information on dominant frequency (F_0) obtained from Table 5.1 is directly used to construct the WP tree. We iteratively detect each WP tree sub-band node until the frequency range of each node includes more than one dominant frequency F_0 . Then, the WP tree of that particular sub-band node will be further split until each sub-band node has only one dominant frequency value or none. After constructing the frequency scale, adaptive frequency scaled WPD is applied to each sampled recording for feature extraction. The detailed description for extracting the features is shown in Chapter 4.2.8.

The difference is that the recording is first split into frames using a Hamming window. Then, all frames are divided into three equal parts, and the WP-feature within each part is averaged, respectively, because different frog species within similar frequency bands may exist in one 10-second recording, splitting each recording into small parts might be able to keep the information of different frog species in the same frequency band. Besides the WP-based feature, two other acoustic features, LPCs and MFCCs, are calculated for the comparison.

6.5.1 Multi-label classification for species richness estimation

Since many sampled recordings consist of calls from multiple frog species, frog call classification can be framed as a ML learning problem. However, previous studies have not adopted ML learning to classify frog calls. Therefore, it is worth investigating different ML learning algorithms for the classification of multiple vocalising frog species. In this chapter, four ML learning algorithms, whose base classifier is a C4.5 decision tree, are employed: binary relevance (BR), classifier chains (CC), random k-label sets (RAKEL and RAKEL1) [Zhang and Zhou, 2014]. The default parameter settings of those four ML learning algorithms are used. The trained classifier, which achieves the best classification performance, is then used to predict the presence/absence of the rest recordings. Lastly, frog species richness can be estimated as

$$F_{rich} = \frac{\sum_{k=1}^K f_{rich}(k)}{K} \quad (6.2)$$

where $f_{rich}(k)$ is the number of frog species of each 10-second recording with predicted labels, K is the number of 10-second recording for each day.

6.5.2 Frog species richness analysis

Different ML learning algorithms are applied on 342 selected recordings to compare different feature sets. Then, five evaluation rules are used to compare the performance with the combination of four feature sets and four ML learning algorithms: hamming loss, rank loss, one error, example based F1, and micro F1 [Madjarov et al., 2012, Zhang and Zhou, 2014]. The descriptions of hamming loss, rank loss, and one error can be found in Chapter 5.3.2. The descriptions of example based F1 and micro F1 are shown as follows.

(1) Example based F_1 is the average of the harmonic mean of instance-precision and instance-recall for every instance. The instance-precision is defined for an instance as the size of the intersection of the set of its predicted labels and the set of its ground truth labels divided by the size of the set of its predicted labels. The instance-recall is defined for an instance as the size of the intersection of the set of its predicted labels and the set of its ground truth labels divided by the size of the set of its ground truth labels.

$$macroF_1 = \frac{1}{Q} \sum_{j=1}^Q \frac{2 \times p_j \times r_j}{p_j + r_j} \quad (6.3)$$

where p_j and r_j are the precision and recall for all $\lambda_h \in h(x_i)$ from $\lambda_j \in y_j$.

(2) Micro F_1 is the harmonic mean of micro-precision and micro-recall, where micro-precision and micro-recall are the precision and the recall which are averaged over all instances and label pairs.

$$microF_1 = \frac{2 \times microPrecision \times microRecall}{microPrecision + microRecall} \quad (6.4)$$

Experiment results are shown in Table 6.1.

The combination of multi-stage PWSCCs + LPCs and the RAKEL1 method achieves the best performance. Therefore, this combination is used for the testing data. Figure 6.4 shows the frog species richness of the three selected sites. For all the three sites, the variation of species richness is not high, which shows that species richness of the same area is relatively stable. However, frog species richness of *BG Creek dam* has a smaller variation over the time than *Kiyomi dam* and *Stony Creek dam*. The comparison of the species richness for the three sites is shown in Figure 6.5. In contrast to other sites, the species richness in *BG Creek dam* is the highest. This might be that *BG Creek dam* is closer to a river and farther away from the human

Table 6.1: Classification results based on four feature sets and four ML learning algorithms. Here the methods for ML learning algorithms are in accordance to the name in the *Meka* software. The base classifier of all methods is decision tree. For a metric, the best value is in bold. Here, \downarrow indicates that smaller values imply higher accuracy, while \uparrow has the completely opposite meanings. The description of each evaluation metric can be found in Chapter 5.3.2.

6.5.3 Comparison with MIML

In this chapter, ML learning is used to classify frog calls without syllable segmentation. Compared with the MIML learning (Table 5.2 in chapter 5), the ML classification has a better classification performance. Although extracting global features for the ML classification will lose some detailed information, most frog vocalisations can still be successfully described

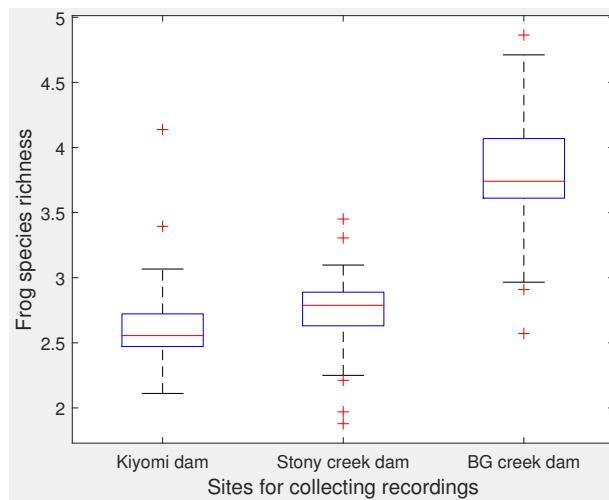

Figure 6.5: Averaged frog species richness of different sites.

when using cepstral features. Compared with other features, global cepstral features are often calculated from each windowed signal. Then, the statistical results, such as mean and standard deviation, of all the windowed signals are calculated, this process will compress the information in the time domain but keep the information of the frequency domain. Since most frogs tend to continuously make calls, the compression of the time domain information will not greatly affect the discriminability of the cepstral features. In contrast, MIML classification needs to conduct the syllable segmentation before feature extraction. However, the use of AED often cannot accurately segment frog calls with low energies, which greatly affects the performance.

6.6 Statistical analysis

Multiple regression analysis is used to explore the relationship between frog calling activity/species richness with weather variables (mean temperature and rainfall)⁵. Both frog calling activity and species richness are found to be highly correlated with mean temperature ($F=5.18$, $P<0.05$ for calling activity, and $F=10.7$, $P<0.01$ for species richness). To calculate the correlation between rainfall and frog calling activity/species richness, we first set the rainfall value as the dummy variable. Then, the correlation between frog calling activity/species richness and rainfall value is also studied with multiple regression analysis ($F=4.63$, $P<0.05$ for calling activity, and $F=4.64$, $P<0.05$ for species richness). The statistical analysis results indicate that frogs tend to make calls in the warm and humid environment, which is in accordance to previous studies [Akmentins et al., 2015, Canavero et al., 2008].

⁵<http://www.bom.gov.au/?ref=hdr>

6.7 Summary and limitations

Acoustic sensors are more widely used to monitor frog calling activity and species richness than the traditional field survey method. However, the use of acoustic sensors generates large volumes of audio data, which makes it necessary to develop automated methods. This paper proposes a novel method for detecting frog calling activity and species richness based on AED and ML learning. Specifically, AED is the first step to calculate frog calling activity. Meanwhile, those 10-second recordings without frog calls are filtered out. For those recordings with frog calls, ML learning is further used for estimating frog species richness with multi-stage PWSCCs and LPCs. Finally, statistical analysis is utilised to reflect the relationship between frog calling activity/species richness with weather variables (mean temperature and rainfall). Experimental results show that our proposed method can accurately estimate frog calling activity/species richness and reflect their relationship with weather variables. Future work will focus on a wider frog call database, including a larger number of frog species, and frog calls collected over a longer period.

Chapter 7

Conclusion and future work

This thesis has addressed frog call classification using both high and low SNR recordings. For high SNR recordings, an enhanced feature set using temporal, perceptual and cepstral features is first proposed. Also, a cepstral feature with a good anti-noise ability based on wavelet packet decomposition is proposed. To classify multiple simultaneously vocalising frog species in low SNR recordings, a spectrum of machine learning algorithms were explored including SISL classification, MIML classification, and ML classification.

Many challenges of this thesis lie in the designing and identifying the effective feature extraction algorithms and adopting novel classification frameworks that can successfully classify low SNR recordings with multiple simultaneously vocalising frog species. Key contributions of this research to the challenges are summarised in this chapter. Furthermore, useful avenues of inquiry for improving the methods described in this thesis are explored.

7.1 Summary of contributions

The contributions of this research are mainly two folds.

1. Feature representation: Identifying characteristics of Australian frog vocalisations and developing corresponding novel features.
2. System integration: Designing a novel framework that combines signal processing and machine learning techniques into a unified and effective system to classify frogs using acoustics.

Below is the summary of the contributions of this thesis:

1) An enhanced acoustic feature set for frog call classification in high SNR recordings.

A systematic scheme was developed towards the goal of automatic classification of frog calls. The performances of various classifiers such as LDA, K-NN, SVM, RF, MLP were evaluated together with different feature sets. The experience gained and experimental results demonstrate that: 1) Compared with previous feature sets, an enhanced feature set including temporal, perceptual, and cepstral features can achieve the best classification performance. 2) The best classification performance is achieved by SVM and RF, in comparison with LDA, K-NN, and MLP. 3) The cepstral feature is very sensitive to the background noise, but can achieve high classification accuracy for high SNR recordings.

2) A novel feature via adaptive wavelet packet decomposition for frog call classification in both high and low SNR recordings.

To improve the anti-noise ability of cepstral features, wavelet packet decomposition is utilised to design a novel cepstral feature. Compared with other cepstral features such as MFCCs and Mel-scale wavelet packet decomposition coefficients, our proposed feature shows both better classification performance and anti-noise ability.

3) Design a MIML classification framework for frog call classification in low SNR recordings.

Since most field recordings contain multiple simultaneously vocalising frog species, both MIML and ML classification frameworks are first introduced to focus on frog calls. For MIML learning, a novel AED algorithm is designed to segment acoustic events using event filtering. Then, different MIML classifiers are evaluated with various acoustic feature sets based on the content and shape of segmented events. Experimental results show that MIML-RBF achieves the best classification results with shape based feature sets.

4) Design a ML classification framework for long-term monitoring of frogs in low SNR recordings.

Different from Chapter 5, acoustic event detection is used for different purposes, which is to filter out those recordings without frog calls. Meanwhile, frog calling activity is estimated based on the shape and content of segmented acoustic events. Then, those recordings with frog calls are classified via ML learning. Three global features, LPCs, MFCCs, and PWSCCs, are calculated to construct four feature sets. Compared with MIML classification, ML classification

can achieve better performance, because MIML classification results are greatly affected by the syllable segmentation process. Although our proposed syllable segmentation method can achieve better results when compared with other methods, the AED result is still not satisfied for classifying frog species. Lastly, the correlation between frog calling activity/species richness and weather variables (mean temperature and rainfall) are studied.

7.2 Limitations and future work

Although our proposed frog call classification system shows promising classification performance, there is still much work that can be done to help scientists and researchers in data collection and analysis in the bioacoustics communities.

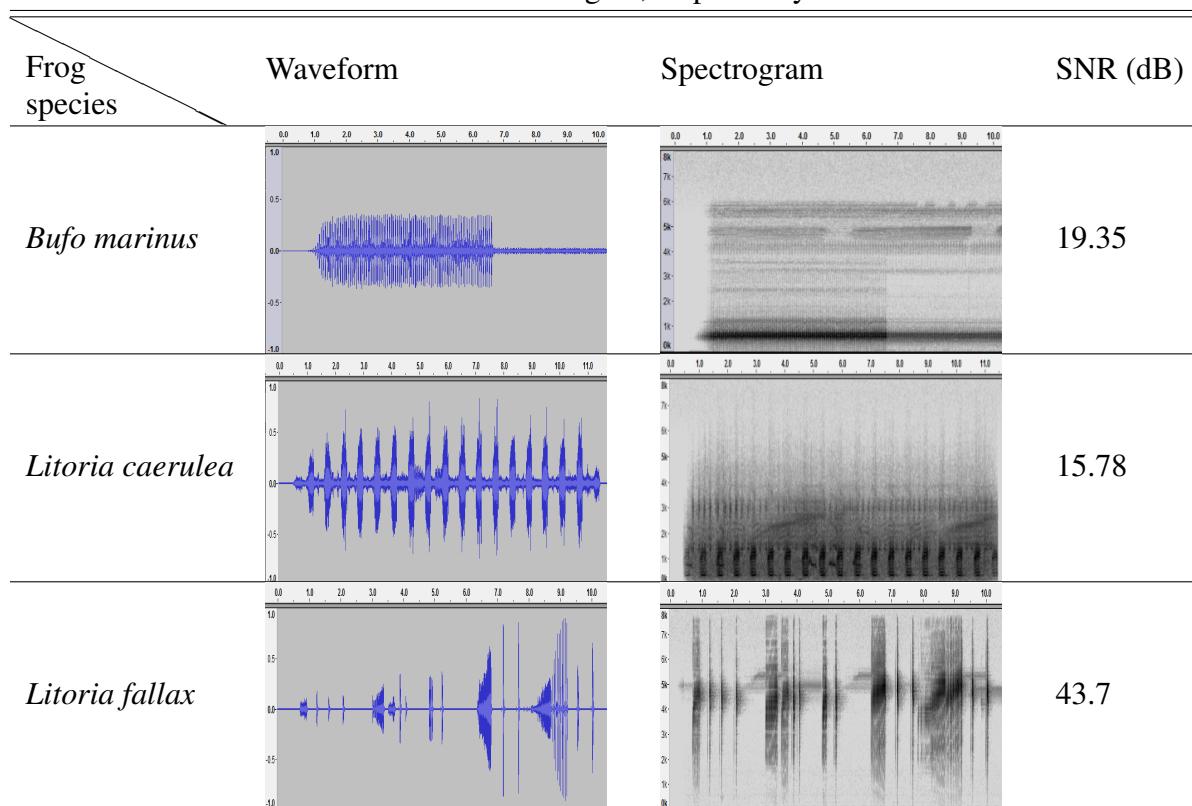

- One of the most important issues when dealing with frog recordings is the need for the standardised species-specific data with behavioural labels. Therefore, the algorithms we developed for frog call classification can be evaluated on a larger dataset. Consequently, researchers can use the outcomes of such automatic call classification methods for field studies effectively and precisely. However, it is very time-consuming to perform manual labelling. It is necessary to develop automatic or semi-automatic methods to perform the labelling.
- Another aspect that requires tremendous improvement is the need for an advanced frog syllable segmentation method for the field recordings so as to extract more accurate event-based features and conduct more thorough analysis on frog vocalisations. The problem of syllable segmentation is very complicated, because there are many simultaneous overlapping calling activities from birds, frogs, insects, and many other sources.
- Since collected low SNR recordings often contain much background noise, it is important to develop effective noise reduction algorithms to improve the classification performance.
- In addition, the *adaptive WPD sub-band cepstral coefficients* feature has been successfully used for frog call classification, which is used to capture the frequency domain information. The time-varying information has been attempted heuristically but there is still a lack of systematic exploration.

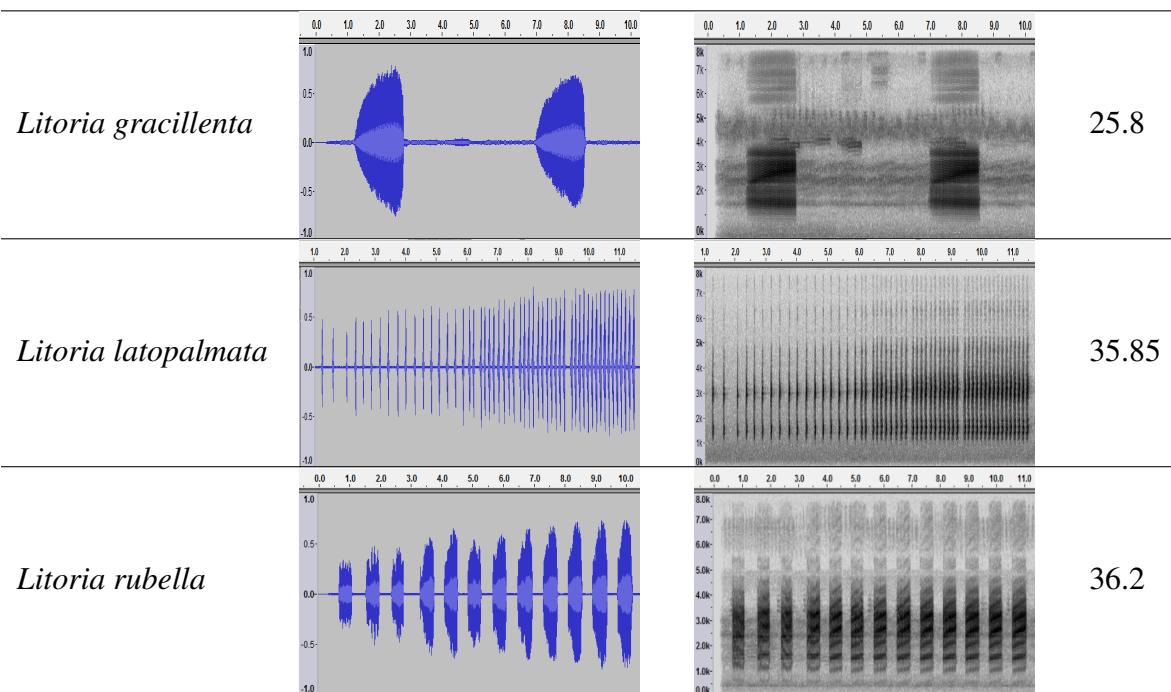

- Chapters 3 and 4 focus on the classification of segmented frog syllables using SISL algorithms. In Chapters 5 and 6, the classification is realised by tagging the small audio clip (10-second recording) with MIML/ML algorithms. There is no direct comparison between MIML/ML and SISL, because MIML/ML and SISL algorithms make different types of predictions, and are evaluated according to different performance measures.
- Our developed frog call classification system aims to help ecologists to study frogs over larger spatial and temporal scales. However, there is still no a generic platform for running the frog calls recordings. It is necessary to develop a toolbox with an easy user interface for frog call classification, and then ecologists can conduct the analysis on their own. We focus on efficacy in this research, however efficiency is also very important in big data analysis. For this purpose, the MATLAB code corresponding to feature extractors and classifiers needs to be optimised to perform real-time frog call classification in the field.

Appendix A

Waveform, spectrogram and SNR of frog species from David Stewart's CD

Table A.1: Waveform, spectrogram, and SNR of selected six frog species from David Stewart's CD. The SNR is calculated as $SNR = 10 \times \log_{10} \left(\frac{\sum_{i=m}^{m+L} S_i^2}{\sum_{j=n}^{n+L} N_j^2} \right)$, where L is the length of the signal and noise used for calculating SNR, and set at 6000 samples, n and m are manually selected start location in the waveform for noise and signal, respectively.

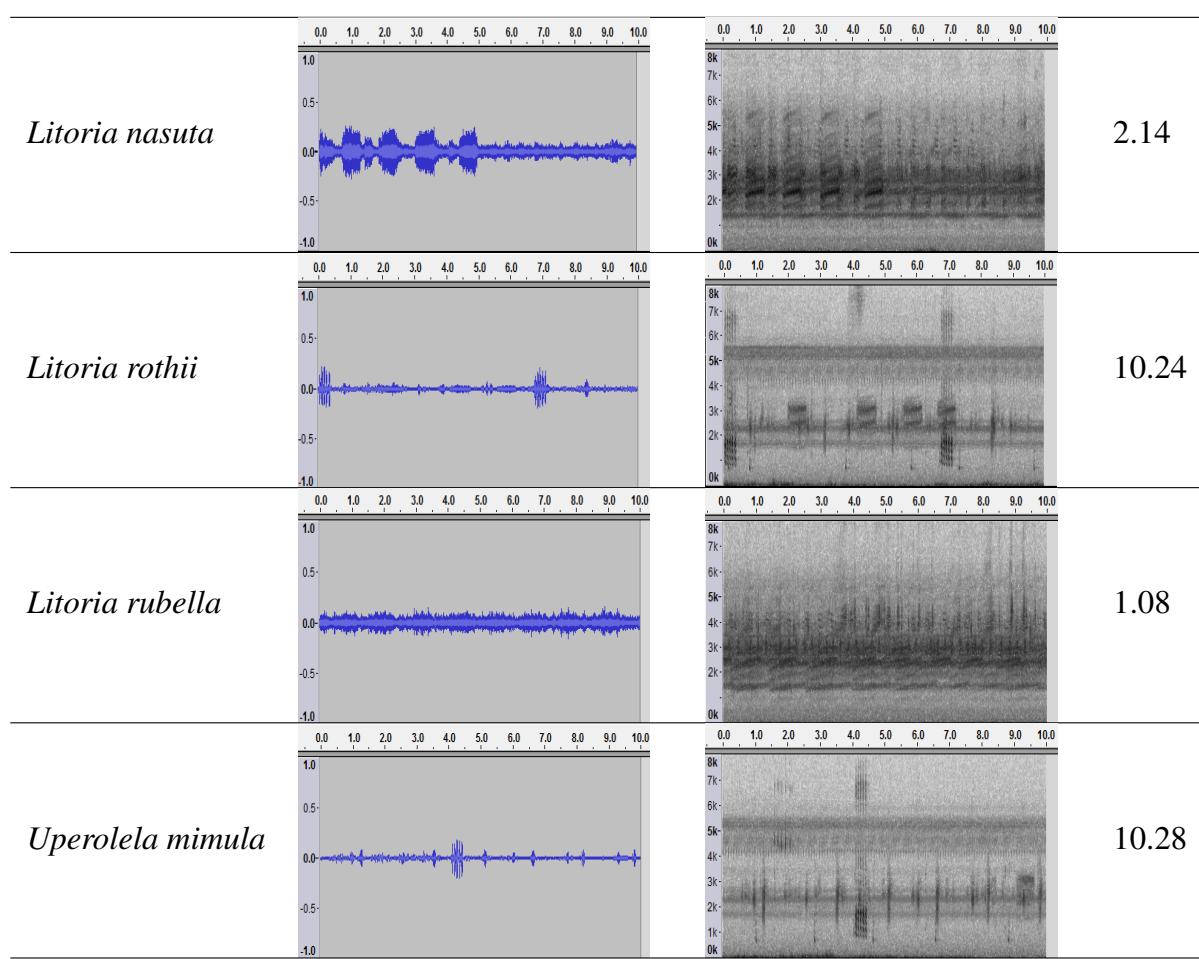

Appendix B

Waveform, spectrogram and SNR of six frog species from JCU recordings

Table B.1: Waveform, spectrogram, and SNR of eight frog species (recordings from JCU)

	Waveform	Spectrogram	SNR (dB)
<i>Bufo marinus</i>			1.86
<i>Cyclorana novaehollandiae</i>			-0.13
<i>Limnodynastes terraereginae</i>			-2.88
<i>Litoria fallax</i>			1.52

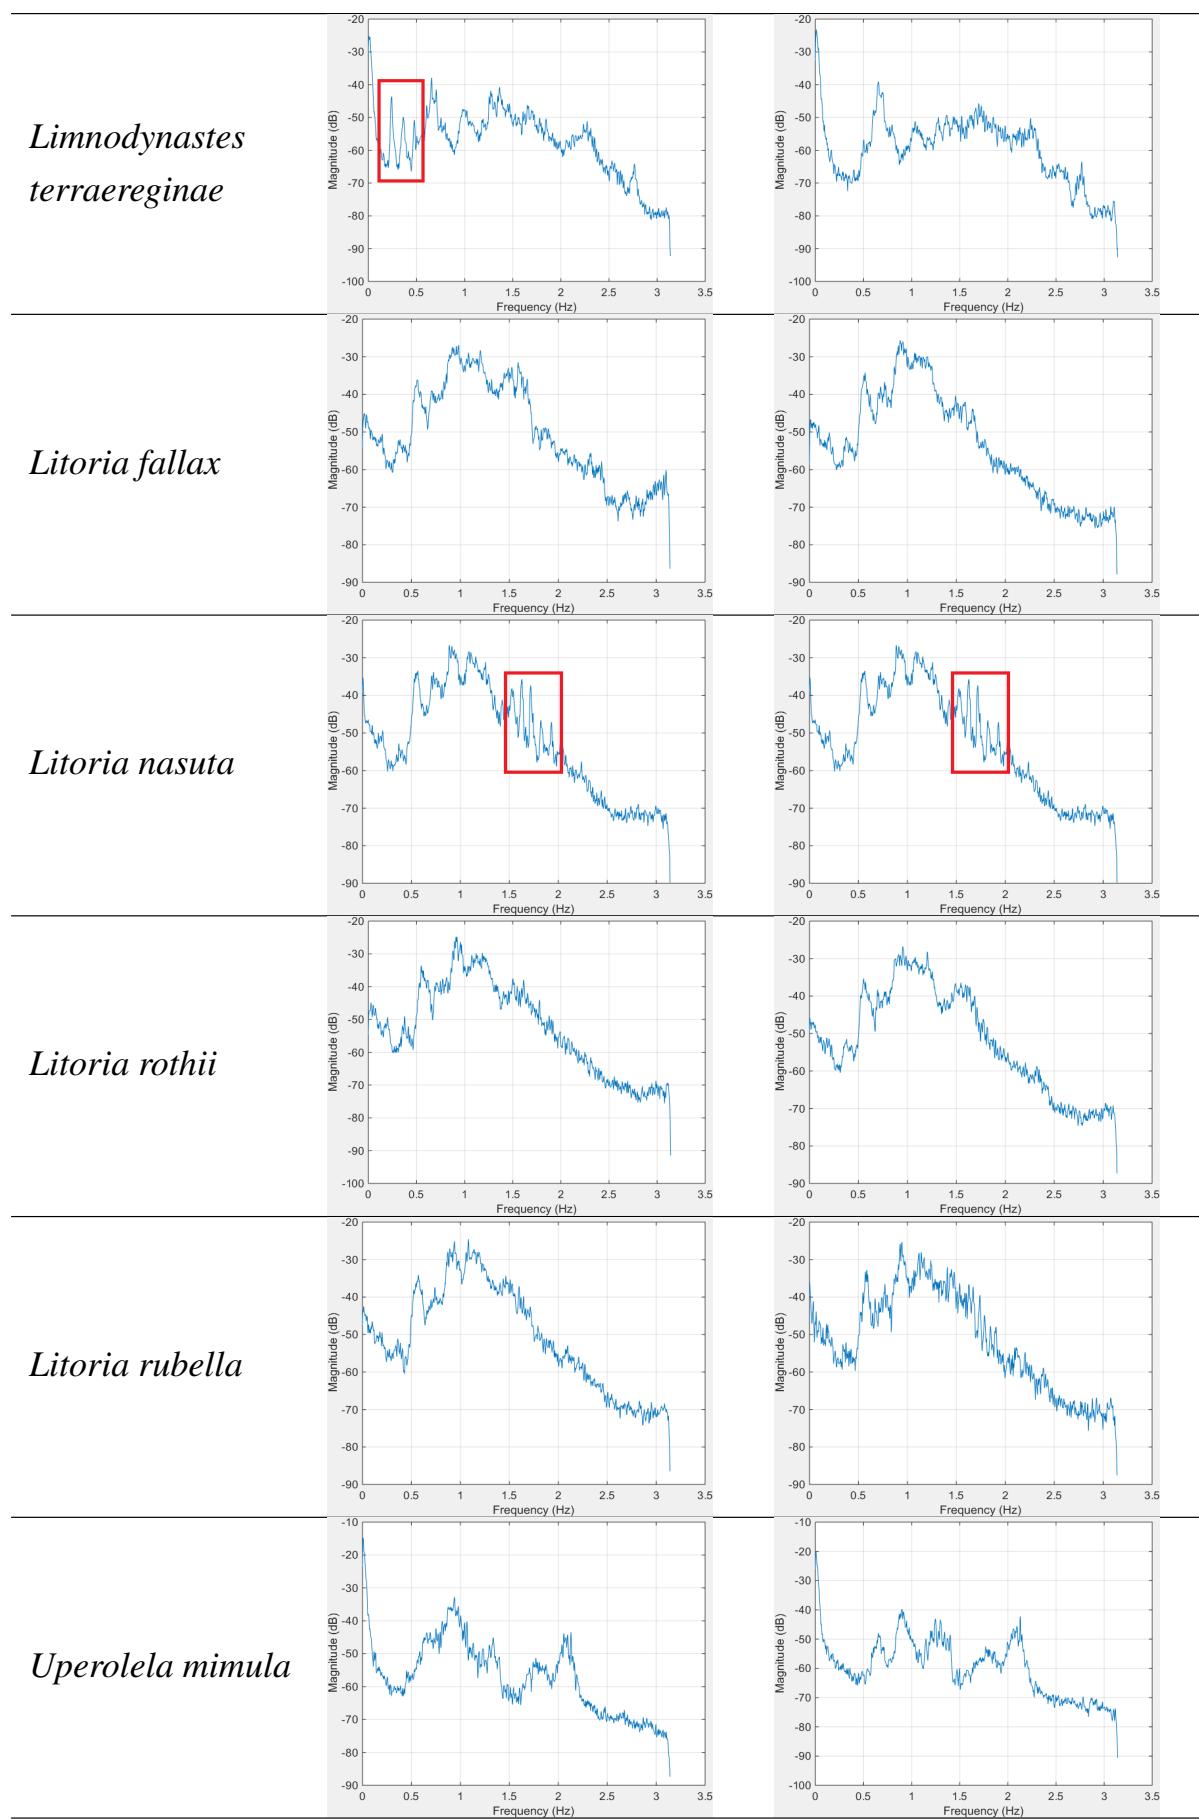

Appendix C

Power spectral density (PSD) estimate of signal and noise (JCU recordings)

Table C.1: Power spectral density (PSD) estimate of signal and noise (JCU recordings); for some frog species, the PSD difference between the signal and background noise is marked with the red rectangle, which indicates the frequency location of specific frog species; for others, the PSD of signal and noise is very similar, which means that some sources have similar frequency information with frog species

Appendix D

Confidence interval of signal and noise

Table D.1: Confidence interval of signal and noise (David Stewart's CD). The calculation of confidence interval is defined as $CI = \mu \pm Z \times \frac{\sigma}{\sqrt{L}}$, where μ and σ are the mean and standard deviation, respectively, Z is the upper $\frac{(1-C)}{2}$ critical value for the standard normal distribution, C is the confidence level, and set at 0.95.

Frog species \ Parameters	Confidence intervals of signal	Confidence intervals of noise
<i>Bufo marinus</i>	$-9.27*10^{-6} \pm 2.10*10^{-3}$	$-2.67*10^{-5} \pm 2.26*10^{-4}$
<i>Litoria caerulea</i>	$-6.73*10^{-5} \pm 2.40*10^{-3}$	$-6.89*10^{-5} \pm 3.90*10^{-4}$
<i>Litoria fallax</i>	$-5.85*10^{-6} \pm 1.50*10^{-3}$	$-2.73*10^{-5} \pm 9.62*10^{-6}$
<i>Litoria gracilenta</i>	$-7.12*10^{-5} \pm 2.00*10^{-3}$	$-7.70*10^{-5} \pm 1.00*10^{-4}$
<i>Litoria latopalmata</i>	$-6.58*10^{-5} \pm 2.70*10^{-3}$	$-1.02*10^{-4} \pm 4.36*10^{-5}$
<i>Litoria rubella</i>	$-3.13*10^{-5} \pm 3.00*10^{-3}$	$-9.87*10^{-5} \pm 4.70*10^{-5}$

Table D.2: Confidence interval of signal and noise for JCU recordings

Frog species \ Parameters	Confidence intervals of signal	Confidence intervals of noise
<i>Bufo marinus</i>	$-1.36*10^{-5} \pm 6.00*10^{-5}$	$-3.22*10^{-5} \pm 4.80*10^{-5}$
<i>Cyclorana novaehollandiae</i>	$1.30*10^{-3} \pm 8.70*10^{-4}$	$1.30*10^{-3} \pm 8.90*10^{-4}$
<i>Limnodynastes terraereginae</i>	$6.43*10^{-5} \pm 1.30*10^{-4}$	$1.86*10^{-4} \pm 1.89*10^{-4}$
<i>Litoria fallax</i>	$2.31*10^{-5} \pm 5.00*10^{-4}$	$5.75*10^{-6} \pm 4.22*10^{-4}$
<i>Litoria nasuta</i>	$-1.55*10^{-4} \pm 4.90*10^{-4}$	$6.25*10^{-6} \pm 3.85*10^{-4}$
<i>Litoria rothii</i>	$-3.32*10^{-4} \pm 9.2*10^{-4}$	$1.61*10^{-4} \pm 2.84*10^{-4}$
<i>Litoria rubella</i>	$-8.15*10^{-5} \pm 5.52*10^{-4}$	$-2.69*10^{-5} \pm 4.87*10^{-4}$
<i>Uperolela mimula</i>	$-1.20*10^{-3} \pm 1.10*10^{-3}$	$-9.36*10^{-4} \pm 3.35*10^{-4}$
